At the autopsy, made on the following day, the œdema of the head, neck, and upper extremity and upper portion of the thorax was still very marked; the peritoneal cavity was normal; the right pleural cavity contained 1,200 c.c. of serous fluid, and there were a number of old and very dense fibrous adhesions over the right upper lobe. The left pleural cavity contained 200 c.c. of serous fluid. The pericardial fluid was slightly increased in quantity. In the upper portion of the chest, just above the heart, and a little more to the right of the median line, was a large ovoid tumor, measuring 11 ctm. vertically and 8 ctm. in its antero-posterior and transverse diameters, and having a circumference of 28½ ctm. The tumor was partly covered by the right lung, which was very intimately united with the tumor. It extended down sufficiently far to depress the parietal layer of the pericardium over the right auricle, and the surface of the tumor was adherent to the parietal layer of the pericardium at this point. It almost completely covered the ascending and transverse portions of the arch of the aorta and the vessels arising from the transverse arch. The heart was slightly hypertrophied. The valves appeared to be normal, although the orifices on the left side were both fairly large, and there had probably been some leakage. The coronary arteries were distinctly atheromatous. On opening the aorta the tumor proved to be a large aneurism, arising from the junction of the ascending and transverse portions of the arch, about 1 ctm. to the right of the origin of the innominate artery. The opening into the sac was round and very large, measuring 4½ ctm. in diameter. The edges were quite sharp and smooth. The sac was filled with post-mortem clots, and there were no layers of stratified fibrin on the inner surface. The entire length of the aorta showed a very advanced degree of atheroma.

The point of interest in the case was a communication found between the interior of the sac and the superior vena cava. The sac-wall was everywhere quite thin—only one to two millimetres in thickness—and, undoubtedly, ruptures had occurred at two points, and the effused blood had been encapsulated, as was shown by two nodules filled with old blood and blood crystals.

The aneurism had markedly compressed the superior vena cava, and the opening leading from the sac into the vena cava was oval in shape, and measured 1½ ctm. vertically by 1 ctm. transversely. The right innominate and the upper portion of the superior vena cava were very much dilated, and had a diameter of 2 ctm. Below this opening the vena cava was so compressed that the lumen during life must have been very largely occluded. A probe passed down from the jugular above, entered the sac of the aneurism, and did not follow the normal course through the lower portion of the vessel. Both the orifice of the right subclavian vein and that of the right internal jugular were guarded by a very perfect bicuspid valve, which had completely prevented the forcing of any blood from the aneurismal sac into these vessels themselves. The force of the blood was expended on the right innominate and upper portion of the vena cava. The wall of the subclavian vein was considerably increased in thickness. The left innominate was found to be completely occluded from a point about 2 ctm. from its origin across to the right innominate, the course of the vessel being along the upper wall of the aneurismal sac. The left jugular was quite moderately dilated, and the walls not specially increased in thickness. The internal mammary vein was quite large, but aside from this no special changes were observed on the left side. The speaker said he had been unable to determine how the blood had been returned from this side, although it was probably through the communicating branches across the front of the neck. The organs of the neck had been taken out *en masse* without knowing at the time of anything unusual in this region. The communication between the sac and the superior vena cava was very clearly an old one, the opening being perfectly smooth and sharply defined. Undoubtedly the opening occurred last April, at the time the patient felt something give way in his neck.

The wall of the vena cava was adherent to the aneurismal sac for a considerable distance below the point of communication.

Localized Empyema.—DR. THOMAS S. SOUTHWORTH presented a specimen of localized empyema. It had been removed from a child in the Nursery and Child's Hospital, aged seven months. According to the history it had been sick for only two weeks, and a diagnosis had been made of broncho-pneumonia. On opening the chest at the autopsy, a cavity was seen lined by a pyogenic membrane, but otherwise dry. This displaced the heart to the left. It was about the size of an egg. Looking underneath the edge of the ribs a small opening was seen in the anterior axillary line, situated close to the ribs, about half an inch in diameter. Inserting the finger into this opening, a cavity was revealed posteriorly, which contained about one ounce of pus. There were a few areas of recent broncho-pneumonia in the other lung.

The interesting feature of this case was the fact that one of these empyemic cavities should be found entirely empty, while the other was nearly full of pus. If an incision had been made in the chest anteriorly during life, the child being in the recumbent position, little or no pus would have been evacuated.

Rupture of the Bladder and Peritonitis.—Dr. James Ewing presented the specimen. The patient, a man forty-four years of age, of alcoholic habits, had been admitted to the Roosevelt Hospital on January 2, 1895. He had been drinking the day before, and was found on the morning of January 2d on the steps of his house. He then vomited and passed some bloody urine. By the time he reached the hospital it was evident that he was suffering from general peritonitis, but its cause was not apparent. Soon after admission he was catheterized, and two ounces of clear urine removed. Its specific gravity was 1.025, and it contained a trace of albumin, uric-acid crystals, and epithelium from the bladder. For the next three days he passed a normal quantity of clear urine, but on January 5th the urine had a specific gravity of 1.032, was alkaline in reaction, and contained a trace of albumin, and apparently gonorrhœal threads. He died on January 8th.

At the autopsy all the organs were found to be normal, except the peritoneum and bladder. The peritoneal cavity contained a small quantity of gas, and was moderately distended with a turbid fluid, said to have had a peculiar odor—probably ammoniacal. No point of origin for the infection could be found until the bladder was reached. The bladder projected into the pelvic cavity like a hen's egg, and was rather thickly covered with fibrin. After taking out the bladder, some of these layers of fibrin were removed, disclosing a lesion in the posterior surface of the fundus. An incision through this coat did not show that the rupture had been complete, but on the inner surface of the bladder, beneath the abrasion on the peritoneal surface, the folds of the bladder were œdematous and infiltrated with blood. There had been, apparently, an attempt at healing, as there was some difficulty in separating the edges of the rent. It was interesting, therefore, to note the occurrence of rupture of the bladder from some unknown cause, and unattended by any symptoms except those due to the peritonitis. It was also interesting to note that after peritonitis had been excited, the process of healing in the bladder itself should have begun, making it difficult to demonstrate the rupture at autopsy. The whole thickness of the abdominal wall in front of the bladder had been carefully examined, and no ecchymosis or any other evidence of injury had been found.

Dr. S. T. Armstrong said that the condition found in the specimen would seem to eliminate an external traumatism. It was possibly the result of catheterization.

The President thought it quite probable that the bladder had been greatly distended during a spree, and that the man had fallen at this time, and had received a blow over the bladder.

Dr. Ewing said that the mucous membrane showed no sign of traumatism, whereas the lesion was evident on the peritoneal surface ; hence it was fair to exclude traumatism from the introduction of an instrument.

Dr. W. G. Le Boutillier said that the urine did not ordinarily contain pyogenic germs, so that its escape into the peritoneal cavity ought not to set up peritonitis. For this reason, one should look for a traumatism or some method by which the micro-organisms were conveyed into the bladder and peritoneal cavity.

Australasian Medical Congress.—The fourth intercolonial medical congress of Australasia will be held at Dunedin, New Zealand, in February, 1896. One of the principal subjects for discussion will be tuberculosis in man and the lower animals.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE ARCTIC WAVE OF WEATHER—THE NEW ELEMENT IN THE ATMOSPHERE—PARACENTESIS PERICARDII—EMPYEMA IN CHILDREN—RESECTION OR INCISION.

London, February 8, 1895.

We are in the midst of a spell of "Arctic weather," as we are told by everyone who stops to say a word. It is certainly superfluous information, for everyone seems shivering, and even the skaters, who have been longing for a good time, admit that it is quite cold enough. Death from cold and exposure is not uncommon, and the mortality of the aged, the very young, and the feeble will certainly be increased. We are not so well prepared for extremes of temperature as you are in New York, so whether from cold or heat, we feel it more. The deaths from respiratory diseases are rising, but there may, perhaps, be a makeweight in some other direction, provided this inclemency does not last too long.

The torpor caused by the cold has fallen upon some of our medical associations, and it is not so easy to excite interesting professional conversation as in more genial weather. Some of one's friends seem as torpid as the new element, and this remark reminds me that Lord Rayleigh and Professor Ramsay seem to have made good their claim to the discovery of the said new element ; at any rate they have brought it before the Royal Society, where the assembled savants expressed satisfaction and offered congratulations.

The discoverers have named the new element "argon," on account of the extreme inertness which seems to be its most characteristic property. It is customary to speak of nitrogen as the negative element in the atmosphere, but it may be called activity itself in comparison with this argon, which may well typify *vis inertia*. It is not yet regarded as impossible that argon may be in reality a compound body or a mixture of two gases. Argon has been liquefied and also solidified, and notwithstanding its inertness it is certain to interest medical observers as well as chemists, for certain physiological effects may be due to it, and in that case its medical aspects will not be overlooked.

The operation of paracentesis pericardii is not very often performed, although some differences of opinion seem to prevail as to its gravity and its value. These were brought out at the last meeting of the Medical Society, when Dr. Percy Kidd related a case which may be fairly called successful, as it gave great relief in a very severe case with granular kidney, cardiac dilatation, and uræmic asthma. In fact it was stated that, except for the tapping, many who saw the case believed the patient could not live many days. He was, however, greatly relieved and continued better for four weeks, death eventually taking place as the result of advanced renal disease. The first tapping gave exit to five fluid ounces, the second to twenty-eight ounces of sanguineous fluid ; the good effects were marked on the circulation, respiration, and secretion. The relief to dyspnœa was very marked, showing that this symptom arose from the difficulty under which the heart was laboring. Dr. Kidd adopted the conclusions of Dr. Samuel West's paper in the "Medical and Chirurgical Transactions," 1883. These conclusions are : 1. That the operation is not only justifiable, but may be safely undertaken with ordinary precautions. 2. The most suitable place is in the fifth left intercostal space, one inch from the edge of the sternum ; but if the pleura be adherent the puncture may safely be made further out and even in the sixth space. 3. The instruments should be a trocar and cannula, with or without aspirations. 4. The

operation may be performed not only in effusions of rheumatic or primary origins, but in those of the later stages of general dropsy, if the fluid in the pericardium is adding to the cardiac difficulty.

These conclusions scarcely met with full approval, for, as pointed out by Dr. Sansom, in some forms of pericarditis the operation could not be justified, and in many was attended with difficulties; and he instanced cases called by Dr. Sturges pamcarditis, with swellings and adhesions, where the presence of fluid was a small point in the case. Mr. Marmaduke Shield also held that the operation was only suited to very special cases, and was by no means so easy or satisfactory as Dr. West's statement made out. Then, Dr. Carr mentioned a case which he had seen post mortem, in which the pericardium was enlarged in all directions, but the heart itself so fixed by adhesions, that in any attempt at operation the needle must have penetrated the ventricle. On the other hand, Dr. Ewart fully agreed with Dr. Kidd and Dr. West, and mentioned several successful cases, and urged the propriety of laying the pericardium freely open, mentioning cases to show that merely inserting a trocar was not sufficient.

Another subject considered at the same meeting was the treatment of empyema in children which Dr. Cautley brought forward in a paper, analyzing 84 cases with a mortality of 16.6. Of 12 treated by aspiration, only 1 died, 1 ruptured externally, and 1 through the lung. Of 35 treated by incision and drainage, 7 died; and of 33 by resection and drainage, 6 died. The duration of after-treatment gave one or two weeks in favor of resection.

Dr. Cautley held that evacuation of the pus is the only sound treatment; aspiration is sometimes useful, but thick effusions will not pass through the cannula, so that the cavity cannot be emptied and it rapidly refills. Resection affords the best drainage, and gives facility for exploring the cavity and breaking down loose adhesions, while there is less danger of hemorrhage and recovery is more rapid. At least, these are the views generally entertained, but, as Dr. Cautley pointed out, they are scarcely supported by this series. Moreover, resection is more severe, should not be resorted to in children under two years, and naturally it causes increased liability to pyæmia and deformities of the chest, so that it should only be employed when a tube could not be inserted without it and when drainage was imperfect, or for the cure of an old sinus. Mr. Morgan said operation would be more speedily effectual if made at an earlier date, as physicians had almost a superstition for the trocar. He preferred resection and thought irrigation useful; Dr. Morison, however, did not approve of irrigation, and thought resection only necessary in neglected cases. From these expressions of opinion we may gather that, much as resection has advanced of late years, the treatment can hardly be regarded as settled.

THE CATHOLIC CHURCH AND OBSTETRICAL SCIENCE.

To the Editor of the Medical Record.

Sir: The importance of the question touched upon in an article on page 147, in the Medical Record of February 2, 1895, entitled "The Catholic Church and Obstetrical Science," shall be my apology for the following criticism:

In said article you have endeavored to prove that the principles of the Rt. Rev. Bishop of Augsburg, Germany, as elicited in his recent pastoral letter, in which he says, *verbatim*, "that it is a sin and morally reprehensible for a physician to induce artificial abortion, no matter how imperatively the safety of the mother demands it," are not in unison with the Catholic Church.

As authority for your assertion that this (the Bishop's teaching) is not the authoritative teaching of Rome you refer to an anonymous writer (whom, however, the editor endorses as "inspired") in the *Münchener medizinische Wochenschrift* of December 25, 1894.

For a preliminary remark I may be allowed to say that, from a prospective stand-point of view, it appears that you have chosen decidedly the weaker side of the case at issue. Here we have on one side a well-known, clear-minded, truthful, very distinguished, and learned prelate, a lawful member of the hierarchy, an authorized judge, teacher, and promulgator of Christian morals. On the other side we have the negative statement of an anonymous writer, whose source of inspiration is not clear, that it is not the "true science" the climax of which is fœticide.

Let us now try the case unprejudiced, unbiased, fair, and impartial. I have the honor of presenting to you the Rt. Rev. Bishop of Augsburg, who says, according to your own quotation, "that the induction of artificial labor, the child being alive, is under no circumstances allowable;" in other words, persists in that the faithful shall obey the Fifth Commandment, "Thou shalt not kill;" to which there is no exception and whereby the end can never sanctify the means. That this is and must be the teaching of Rome is self-evident, and consequently binding upon all the faithful who recognize the authority of the Catholic Church; but to clear the Bishop beyond a reasonable doubt we will now give evidence which the most sceptical must accept that the Bishop is no heretic, but in his full right, and that his teaching is also the teaching of Rome.

As far as Dr. Wirthmüller is concerned, I am unable to trace his authority, but would be thankful for information and quotations regarding him. In his place I put, first, A. Köning, an author who is in this country universally accepted. He says plainly that the induction of premature labor is homicide, even at a stage when the fœtus has not yet life. He refers to the dogma Immaculatæ Conceptionis B. M. V., of which we take the following extract: "*Nunquam licet directi procurare abortum*" (It is never allowed to produce directly an abortion). See A. Köning's "Theologia Moralis," vol. i., No. 474. To save space I refer only to the theological works of S. Alphons Liguiri, L. iv., No. 394, and Lacroix, L. iii., p. 1, No. 823, upon whose teachings Köning has based his assertions and decision as they are authorized by Rome. We have also consulted Lehmkuhl, and find in his works nothing contradictory to the teaching of the above-named authors, the Bishop of Augsburg, or Rome.

We find in his book the decision of the Council of Baltimore, which is *that it is not allowed*, that it is "a sin and morally reprehensible" "to induce artificial abortion, no matter how imperatively the safety of the mother demands it" (Lehmkuhl, Part I., No. 848).

On the following page Lehmkuhl cites the letter of the assembled bishops in Baltimore to the Holy Congregation of the Inquisition, in which they ask if it was right to teach that it was allowed, under certain conditions, to produce abortion, to which the prompt answer came: "*Tuto doceri non posse*" (It cannot be taught at all), R., signed Cardinal Monaco, Secretary of Congr. Inquisition. We think we have given sufficient proof, or at least the keys to proof, that the Rt. Rev. Bishop of Augsburg is in the right and the anonymous "inspired" writer wrong.

Now a few remarks upon your own statements and your logic. You recall a judgment of cardinals in Rome which was given in favor of craniotomy or any operation directly tending to destroy the life of fœtus in utero, *i.e.*, "Rome did not condemn this operation if performed under the authority of approved medical teaching and in the interests of the mother." Mr. Editor, I fear your memory does not serve you well and I advise you to look up the case. I am sure you will not find a decision from Rome where the destruction of the fœtus under any pretence is sanctioned. You

will find, perhaps, that means which save the life of the mother directly, and may cause the death of the child indirectly, are, under certain conditions, allowed. Whatever those means may be, they must have the double effect of saving the mother and not necessarily and directly killing the child. This is the teaching of Rome to the extremest extent. A premature delivery not necessitating the death of the child may, under certain conditions, be allowed. Craniotomy never!

Your logical as well as conservative opinion, "If it is wrong to take one life to save another, it cannot be lawful to suffer two lives to be destroyed when one might have been saved," I let stand at its face value.

Just one more question: Who saves or destroys when in case of craniotomy both mother and child die? I think statistics have shown that in craniotomy thirty-five per cent. of the mothers have died, in addition to one hundred children killed, while in cases of Cæsarean section there was only a death-rate of forty-eight per cent. in all. Compare this, and you have a saving of 87 lives. Of course you have here against the lives of 100 children the deaths of 13 mothers. Whether or not these 13 mothers, if saved, are worth more than the 100 children is a question of wide range. It seems, however, against the law of nature to destroy proper metamorphosis in its fruit, selfish and brutal in its very nature indeed. It is surely not the teaching of Rome! Herewith we have, I think, finished our case.

JOHN HUND, M.D.

CHIPPEWA FALLS, WIS., February 13, 1895.

HOW MEDICAL CHARITY IS ABUSED.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It has been some time since the MEDICAL RECORD has raised its voice against "The Dispensary Evil." I trust you have not become discouraged or have concluded to remain silent on a topic so important to the readers of the MEDICAL RECORD. The more I see of dispensary service the more I am convinced that some reform should be inaugurated, and only those unable to pay for medical attendance should be entitled to the privileges of such service. It is the dispensary doctor whom we should censure. He treats every patient that comes, with the hope that he may now and then "run in" to his office some who are able to pay a trifle. We who do this are "cutting our own throats," if we but knew it. Over and over again cases are treated that in no way should be recognized. The evil was forcibly brought to my mind only the other day. A woman, keeping a fashionable boarding-house in the neighborhood of Madison Avenue, always visits a dispensary when she requires medical service. Were she to moderate a little her bibulous propensity and pay for medical attendance out of such savings, I am sure she and some striving doctor would both be benefited. In the same house, the wife of a man who receives a salary of $2,800 per annum, has for months attended the free out-door department of a hospital here in New York. Another case, and, mind you, this is in the same house, a man with rheumatism receives free electric treatment at a dispensary. His wife earns $50 per week, on the stage.

Now, is this fair? If one household produces such instances, is it not fair to presume there are many others of like character. The young, and sometimes old, doctor, who walks to the dispensary because he wishes to save car-fare, is imposed upon by such cases every day in the year. In contrast to this, look at the services our legal fraternity render to the poor. What are they? None at all. Recently a friend had occasion to consult a law-book. Not being a member of the library, he was not allowed to look into a book at any of the law libraries in this city. Why? Because lawyers don't wish laymen to find out any point of law unless they consult a lawyer and pay for the advice. We doctors should know the dignity of our calling, and be entitled to proper compensation from those who can pay. I am sure the income of doctors would be greater than it is to-day were the dispensary service more guardedly performed. As a reform measure, I would suggest that all patients seeking treatment should first be obliged to make application at the office of the United Charities Organization, and receive from that body a ticket signifying that the holder is a proper person to receive dispensary service.

Yours truly,

OLD SUBSCRIBER.

February 15, 1895.

CORPORAL PUNISHMENT FOR FELONIES AGAINST THE PERSON.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: If the records of police station-houses, or the court proceedings and examinations of police magistrates, could be opened to the public, sentimentalists would soon find reason to change their views regarding the necessity for corporal punishment for certain crimes. But public decency forbids the newspaper publication of the facts. A professional and official experience of many years in the downtown district east of the Bowery and extending to the East River has convinced the writer that the prevalent methods of punishment for the crimes alluded to are notoriously inadequate. The population of this district is largely made up of foreigners of the lowest classes of Continental Europe, with the addition of many Chinamen, and the crimes and attempted crimes against the persons of children by these degraded wretches are revolting in the extreme. Instances coming under my personal knowledge might easily be multiplied, but their recital would only fill sensitive and unsullied minds with horror and disgust. But as physicians and sociologists the question that concerns us is the famous one: "What are you going to do about it?"

What would be thought of the surgeon who, discovering a malignant excrescence on the body of a patient, would hasten to conceal it under the immaculate folds of a white bandage lest it offend the public eye, and neglect to apply thoroughly the eradicating knife, even at the risk that some squeamish onlooker might faint at the sight of blood? Yet there is a social cancer threatening the lives and purity of those children whose parents, by force of poverty or other circumstances, are compelled to bring them up in sections of this great city where morality is an unknown quantity to the hundreds of criminal outcasts from other lands to whom this country opens its hospitable shores. Are our present laws sufficient to hold this danger in check? It has been held by those who oppose corporal punishment that it is vengeful. No law of the State has any right to exact revenge. State laws have three functions of punishment, medicinal, deterrent, and retributive. As punishment is medicinal, it serves the offender; as it is deterrent, it serves the commonwealth; as it is retributive, it serves the offended party, being a reparation offered to him. Beyond and above any law of the State, there is the Eternal Law which says that every creature should act in the mode of action proper of its kind, and to the Author and Creator alone belongs vengeance. But the judge who orders, and the castigator who inflicts, corporal punishment are not animated by a desire for revenge. Theirs only to see that the State which they serve fulfils its whole duty in protecting its members, by deterring the evil-disposed from crime. The same minds which shrink from the infliction of corporal must also advocate the abolition of capital punishment. "Whoso sheddeth man's blood, by man shall his blood be shed," may seem to them to be a relic of bygone barbarity unsuited to this altruistic age. Yet where is the State to-day with its men so ideally virtuous that the right to visit gross crime with death can do otherwise

than strengthen their virtue? The writer does not share the conviction of a recent accomplished writer in the MEDICAL RECORD that we are daily becoming more degenerate, but he has daily brought to his mind the fact that unbridled passion and lust are still as rampant as they were twenty-two hundred years ago, when Aristotle wrote that the multitude obey on compulsion rather than on principle, and from fear of pains and penalties rather than from a sense of right. Although the day may come when capital punishment may be practically abolished by reason of the extreme infrequency of its employment—a consummation devoutly to be wished—yet the power to inflict it must always remain latent in the State. No government yet has dared to renounce it.

This proves that the human mind universally recognizes that the first condition of appropriate punishment is that it be manifestly proportioned to the crime. "Not the least appalling thing about crime—atrocious crime especially—is the example that it gives and the imitators whom it begets," says an able writer on moral philosophy. And, continuing, he says, "The one preventive is to append to that deed a punishment, the image of which shall also enter into the mind, excite horror, and disenchant the recipient." Of what corrective use is it to take a brutalized, half-fed, ill-housed loafer from the streets for a time, and ensconce him among the comforts of a modern penitentiary, with its regular hours, regular meals, and safe shelter from inclement weather? Is such punishment medicinal, deterrent, or retributive? And yet a recent discussion at the Society for Political Study (*New York Herald*, February 13, 1895) brought out the suggestion that convicts be employed in ornamenting their cell walls and embroidering their own garments, in order to awaken a love of the beautiful. Murderers awaiting execution are deluged with flowers and sympathetic notes from that portion of the community which forgets that the victims were hurled into eternity without warning, as the result of a deliberately conceived plan.

It is alleged that corporal punishment deprives man of one of his congenital and inalienable rights, to wit, personal dignity. But every right has a corresponding duty, and the correlative duties of the right to personal dignity are sobriety and chastity, duties which bind always and for always. What can further degrade a man who has sunk low enough to commit a crime against nature? "He hath matched himself with senseless beasts and become like unto them" does not fitly describe him. He has gone lower than ever beast was known to go. Let those who think the picture is overdrawn examine for themselves the conditions existing among certain people of this city, never alluded to in polite society. Let them understand the corrupt influences at work, sapping the very vitals of our youth in unnatural sexual practices. The pages of Suetonius are mild by comparison with what actually occurs every day, even, and especially so, in the so-called intelligent and educated classes.

Krafft-Ebing has described nothing which cannot be duplicated here, if those are to be believed whose duty throws them into contact with vice. Are these people votaries of vice or are they insane? If the latter, some lunatics are filling positions of great responsibility and trust.

Corporal punishment, or the fear of it, may yet prove to be the only wholesome means of checking the spread of this moral pestilence, but its causes, prevention, and treatment open up too wide a topic to be discussed in this paper.

CHARLES E. NAMMACK, M.D.,
Surgeon of Police, New York.
29 EAST TWENTY-FOURTH STREET.

"The Practitioner."—Dr. Malcolm Morris has assumed the editorial management of this journal, his duties beginning with the new year.

WHAT IS THE PARTICULAR TREATMENT?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a recent issue you published a very interesting article by Dr. Illoway, of New York, on nervous dyspepsia, in which he stated that he had achieved a degree of success in the treatment of that condition to which my efforts have been directed as yet without satisfactory results. In a later number of the MEDICAL RECORD he was asked to give his treatment, and that request remains without published response, I believe. I cannot believe that it is due to any reluctance on the part of the doctor to let his brethren of the profession know of his method, but think that he may have replied by letter directed to the writer who asked for information. I am another who would like to be instructed in the good way.

At present, the results obtained by Dr. Illoway, if produced in several of those who depend on me for help, would give great happiness to them, and corresponding gratification to me. Can I hope to get the desired help through the columns of your excellent journal?

Very truly yours,
H. L. MANCHESTER, M.D.

PAWLET, VT.

THE LATE DR. LOOMIS.

TO THE EDITOR OF THE MEDICAL RECORD

SIR: With your kind permission I would like to add my little tribute to what has already been said, and well said too, by Dr. Rupp, in the last issue of the MEDICAL RECORD, concerning the characteristics of the late Professor Loomis.

To the thousands of students who had the pleasure of listening to Professor Loomis's lectures, the announcement of his death must have come, as it did to the writer, as a sense of personal bereavement.

His was not the nature to immediately attract those who came within the sphere of his influence; on the contrary, there was something in that robust, sturdy form that appeared to be actuated by a spirit, if not of repulsion, at least of aggressiveness. But as time passed on and one grew to know him better, the streaks of kindliness which now and then flashed from the impulses of his generous nature served but to heighten and intensify the love and admiration the students bore him.

Loomis was unquestionably a great teacher, but by no means a brilliant one, if brilliancy means a display of pyrotechnic eloquence which left the student lost in admiration of the style of his utterances, but compelled a small share of passing attention. But if true eloquence is characterized more by what is said than in the manner of saying, then Professor Loomis was truly eloquent. The plain, concise method he adopted in imparting information, the thorough ventilation of every subject he undertook to teach, and the splendid manner in which he seized upon the salient features of the different diseases while giving clinical instruction, illuminating them from the vast storehouse of his individual experience—these will long linger in the minds of the thousands of students who had the good fortune to attend the University during his connection with that able institution.

Beneath a bluff and somewhat aggressive exterior the waters of a kindly nature pursued their even course, undisturbed by the animadversions of carping critics. While ever open to conviction, yet once he had marked out the path he was to follow he walked it unflinchingly. To the students he was ever fair and just, and it was on this account he was less feared than many others when the finals took place. He was a man of uncommon soundness of judgment and of rare common-sense. And, Mr. Editor, it is the men of sound judgment who leave their impress upon the

character of our institutions, medical or otherwise, rather than the brilliant minds whose flashes are too far above the earth to effect any permanent good. And to us old students, who have passed beneath the portals of our dear Alma Mater without forgetting her interests, it is a source of regret and sorrow that the voice of Loomis will no longer be heard in her councils.

The University has had many eminent men among its corps of teachers, men whose names have gracefully and deservedly borne international reputations; but among them all there is none whose name is so closely and intimately associated with her best progress and development as that of Alfred L. Loomis. And if it be true that life is not to be measured by the mere passing of the years, but by the amount of work performed and of good accomplished, then, judged by such a standard, Dr. Loomis passed more than the allotted time of man upon earth.

There are many professors still connected with the University whose names are endeared to the old students of a decade of years ago, for one reason and another, but among them all that of Loomis, *illustre et venerabile nomen*, stands prominent.

JOHN J. MORRISSEY, M.D.

HARTFORD, CONN., February 8, 1895.

MALARIA AS A WATER-BORNE DISEASE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Replying to Dr. Dalrymple's letter of January 26, 1895, the Doctor says I "stand alone as an individual" in the views I have given to the profession on the subject of malaria as a water-borne disease. I may have stood alone, but I no longer do so, since the wide-spread audience your broadly disseminated journal gives one has elicited an interest in this subject among the brightest minds of the profession, and I have therefore been the recipient of scores of private letters giving the most gratifying assurance that the authors have made observations that bear the best evidence we can now command that the position I am led to contend for is worthy of the calm, earnest, and active consideration of the profession, in the fact that their observations agree with my own. In my second article, read before the Mississippi Valley Medical Association at Hot Springs, Ark., last November, a few of their letters are quoted from.

When one makes statements it is always proper to do so from reasonably accurate premises, and it must be clear to everyone who has done me the honor to read my articles that if the desire is only to subvert them, rather than to get at the facts, such a person should at least come to the subject with hands clean of personality, epithet, and sophistry, and the statements made as to conditions that might be supposed to refute my position ought to be based first upon a fair and uncolored quotation of my assertions.

Now let us examine how far Dr. Dalrymple has done this: He states the water-supply of New Rochelle is "considered good." He, however, must also state to the intelligence of the nineteenth-century up-to-date readers of the MEDICAL RECORD how and why it is "considered good." He should tell us that the water has been tested by experts, and who they are, and that in no instance was the palustral parasite found, and therefore the water is "considered good;" as he does not do this we are left open to the possible doubt as to whether the water is actually worthy of being "considered good" simply because there has been no evidence given your readers that it is good and demonstrated to be free from palustræ by means within the reach of well-informed medical men.

He states that every care is taken to prevent contamination in these (surface?) springs that supply the village. He must also state, for the judgment of your self-thinking scientific readers, what care is taken; they can then judge of the adequacy of the care for themselves. He states in his first letter, in MEDICAL RECORD of November 10, 1894, that the persons attacked (with malaria?) were of all nationalities: Italians, Irish, Germans, Swedes, negroes, and last but not least, native-born Americans. In his last, of January 26, 1895, he tells us the persons attacked were "Italians all." Which statement are we to believe, or are we to take him seriously at all as knowing the facts?

He says that Italians don't run to doctors with malaria. Are we, therefore, not to infer that he didn't see or examine any of the alleged cases at all, by examining the blood for the presence of the palustral parasite, always present in palustral fever—an easy, simple, and necessary precaution to enable him to say that the cases were really malarial and not something else? or did he, in the report of these cases, do as he says he did with reference to his lay neighbors whom he says attributed their sickness (malaria?) to the digging up of the ground, and "I [he] certainly agreed with them."

What an assertion for a medical man, who ascertains the lay diagnosis, and "certainly agrees with" the lay diagnosticians, and this in the light of all the facilities for accuracy of diagnosis possessed by nineteenth-century medical science for the investigation of suspected cause, existence, and effect that would place the diagnosis, source, and existence of malaria beyond the realm of mere lay medical opinion or moss-grown dogma, by which the doctor by his own word admits he was guided.

He says his little boy had also malaria, but he did not get it through any water or milk, for both were sterilized, and that quinine, etc., were useless in his child's case. The treatment refutes the accuracy of his diagnosis, as the well-known specific power of sulphate of quinine to destroy the palustral parasite in the blood has been too well demonstrated to make it necessary here to say that the therapeutic history of the case bears the suspicion of mistaken diagnosis.

He says the water and milk used by the child were both sterilized. There must have been a query in the minds of the readers of the MEDICAL RECORD as to what were the methods of sterilization, as more than half of them known to the profession are worthless in practical results.

I may be allowed to intimate that it yet remains to be proven that the palustral parasite is not transmitted through the blood of the cow into the milk, just as tubercle bacilli are. These investigations will go on, and all the avenues will be considered by the profession that can possibly be inimical in the introduction of the palustrae into the human organism.

It is also yet to be demonstrated that the parasite does not find a nidus in the tissues of the several edible ground vegetables I have spoken of heretofore, as well as melons and other ground fruits. The source of ice added to sterilized water ought always to be considered.

He says the New Rochelle water-supply is from springs, and has a fall of one hundred and eighty feet in one thousand. What is the bearing of this statement on the question? Are we to infer that such a fall is fatal to the palustral parasite?

He says he does "not question my long experience, accurate and original investigation, but I say (he says) his (Daly's) field and time have been limited in comparison with others."

Limited, forsooth; limited to a range of swamp and malarial region from Manitoba and the Red River of the North, and along the Atlantic coast to Florida, to Cuba, Yucatan, and other States of Mexico, and through more than thirty States of the Union; limited to an area inhabited by more than fifty millions of people; limited in time to a period of over twenty years. Certainly we must take his statement of "limited" in a Pickwickian sense.

Respectfully, W. H. DALY, M.D.

PITTSBURG, PA.

SCIENTIFIC VERSUS OBSCENE MEDICAL LITERATURE.

To the Editor of the Medical Record.

Sir: Under the above heading, you published in your last number an editorial, which presumes to believe that for some reason or other, medical literature could be excluded from its present mail privileges if obscene literature were, through the passing of a strict and special law, prevented from enjoying them.

Permit me to copy the wording of the bill proposed by me for the consideration and acceptance of the Medical Society of the County of New York, and of the New York Academy of Medicine. They were as follows:

"Be it enacted, etc.,

"That medical books, pamphlets, and circulars, the contents of which are of a character not proper for general and indiscriminate perusal or circulation, shall not be admitted to nor transmitted through the mails unless enclosed in sealed envelopes or wrappers, and prepaid at letter rates of postage, *or unless addressed for delivery to or in care of physicians, surgeons, medical schools or colleges, or students in such schools or colleges, or to dealers in medical publications, and directed to them as such.*"

It appears, Mr. Editor, you overlooked the last clause of the proposed bill altogether. If it were passed no medical journal or book would be interfered with, indeed, medical men and students, schools and dealers, would still enjoy the advantage of receiving, free of cost, their advertisements of "Dr. W., female specialist," of the "Power Wafers," of the "Constitutional Tonic Wafers," of the "Way of Escape," etc. It is true our boys and girls would not so easily be reached by the miscreants, as hitherto. Nor would they be told where the office can be found, and when, and at what price, where their bodies may be defiled, and their souls contaminated. A prominent postmaster in the United States received the following note from a father: "The enclosed disgusting pamphlet was received through the mails by my son (fifteen years of age) yesterday. I do not know whether it is a violation of the postal regulations to use the mails for transmission of matter of this kind, but I consider it decidedly indecent and demoralizing." This note was accompanied by a glaring circular describing "how the celebrated Sultan's or Turkish wafers came to be introduced to Americans." It was the same postmaster who suggested to me the bill as printed above. It is at present in the hands of the Hon. E. J. Dunphy, a representative of this city, who is a member of the House Committee on Post Offices and Post Roads. I do not say it is the best possible bill, but it is a better one, and more efficient than you supposed it to be in your editorial of last week, and does not in the least interfere, as you will now admit, with the unhampered circulation of *medical* journals, magazines, pamphlets, or books. It will, when passed, protect to a certain degree against the filthy sheets disseminated by quacks as privileged mail matter.

You, Mr. Editor, and your colleagues of the medical press, have great facilities in impressing and directing the conscience of the medical profession and the public at large. As that is so, your duties and responsibilities are just as great, and I fully believe you will benefit the community by again studying, and then recommending (amended, perhaps), and urging upon the representatives of the people, the bill introduced by me at the suggestion of a gentleman who had great opportunities to learn of the vast amount of obscene literature distributed over the country, under the protection of the law of the land.

Very sincerely yours,

A. Jacobi, M.D.

110 West Twenty-fourth Street, February 26, 1895.

[After this explanation we not only agree perfectly with our distinguished correspondent, but give the measure our heartiest endorsement.—Ed.]

New Instruments.

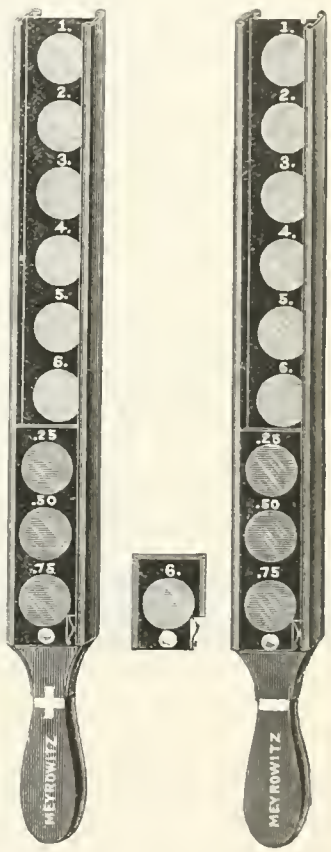
A LENS-HOLDER FOR FACILITATING RETINOSCOPY.

By WILBUR B. MARPLE, M.D.,

Assistant Surgeon New York Eye and Ear Infirmary; Adjunct Professor of Ophthalmology New York Polyclinic.

Long since the writer became convinced that in the determination of refraction the method of examination known as retinoscopy, or better, skiascopy, surpassed in accuracy almost all other methods. On account of the comparative cheapness of the apparatus or instruments necessary, it commended itself, moreover, to many who came under his instruction. The only drawback has been the inconvenience of changing the lenses on the face of the patient, seated as he is a metre away from the observer. The following device has been used by the writer for over a year, and is submitted to the workers in this department of medicine with confidence that it will prove to be as great an aid to others as it has been to him.

As is seen by the figure, it consists of a frame (containing a series of lenses) which the patient holds by the handle in front of the eye under examination. Two frames, one containing convex and the other concave lenses, are all that are necessary. The number of lenses in each frame and the variations in their strength are matters of individual taste. After using various combinations, the writer now employs a series of six lenses, beginning with 1 D. and going up to 6 D., each lens of the series being 1 D. stronger than the one preceding. This enables one quickly to determine the error to within 1 D., provided this error is not greater than 5 or 6 D. For those unusual cases where the error is greater, there is a small sliding frame behind containing a single lens of 6 D. which can be quickly slipped up over the other lenses, one after the other, making the combinations of 7 D. up to 12 D. Where one desires to determine the error more closely than within 1 D., there is a small sliding frame in front containing three lenses, 0.25 D., 0.5 D., and 0.75 D., which can be slipped up over the others. In the frame containing the convex series the writer employs as the fractions concave lenses; in the frame containing the concave glasses, the fractional lenses are convex, for reasons which will be at once apparent.



The method of employing it can best be illustrated by our case. Let us say our patient has a hyperopia of 2^{5} D. He takes the holder and places it vertically before the eye so that he looks through the top lens (+ 1 D.). The observer sees at once that this is not strong enough, and accordingly the patient is told to move the frame up so that he looks through the next lens (+ 2 D.). And so we continue until we reach + 4 D., when we see that we have over-corrected. We then slip the small

frame up till its first lens (— 0.25 D.) covers the + 4 D. (—0.25 + 4 D. = + 3^{75} D.). We see that the error is still overcorrected. We slip the next fractional lens (—0.5 D.) up over the + 4 D. (= 3^{5} D.). Now we observe that the error is just corrected, and this has all been done in a very few moments. There is a small spring clip on the small sliding frame, which snaps into a little slot just when the moving fractional lens is exactly over the other.

At the suggestion of Dr. Gruening, a metal flange was attached at each side of the frame. (See figure.) These prevent the holder from resting immediately in contact with the face or forehead, and thus soiling of the lenses by the perspiration or oil of the face is avoided.

With this device the writer has determined with great rapidity and accuracy the refraction of a large number of cases in a large clinic, which cases included not only simple myopia and hyperopia, but also cases of astigmatism—compound, simple, and mixed.

In conclusion the writer would refer to one immense advantage of retinoscopy over the ophthalmometer. In the determination of the amount and axis of the astigmatism, the finding of the ophthalmometer leaves little to be desired. But as to the kind of astigmatism, it gives us no clew. It may be all hyperopic, it may be all myopic, it may be partly one, partly the other, but as to this the ophthalmometer tells us nothing. On the other hand, when we have completed our examination with retinoscopy, we know exactly the amount of the astigmatism and exactly how much of the entire amount is hyperopic and how much is myopic. This to the writer seems an immense advantage.

(The lens-holder is made by Meyrowitz.)

A NEW, NON-CONDUCTING SPECULUM FOR USE IN POST-PARTUM AND POST-ABORTUM INTRA-UTERINE DOUCHING.[1]

By EDEN V. DELPHEY, M.D.,

NEW YORK.

About two years ago, I had a severe case of puerperal septicæmia, in the treatment of which I desired a speculum which would enable me to irrigate the uterus

with hot water—in fact, so hot as to cause pain to the sensitive perineal surface. Believing that all sorts of specula had been invented which could be invented, I tried the instrument-makers for such a one, but without avail.

I have experimented with several different shapes, sizes, and forms of blades, handles, etc., during this time, and have decided on the one now presented. It is made of hard rubber, vulcanized on the mould, and will therefore retain its shape no matter how hot the water is in which it may be placed. The blade is similar to a Sims, but without the duck-bill tip. The handle is simply a prolongation or continuation of the bottom and sides of the blade, and is joined to it at an angle of about seventy-five degrees, the handle forming a trough for conducting the solution and débris to a receptacle beneath. The edges of the trough-handle are slightly cut away, about half-way down, to afford a better grasp in holding. At the bottom are two notches and a hole to which the bail of a pail can be either hung directly or fastened by means of a hook, thus making the instrument self-retaining in certain cases.

The instrument is intended for use in post-partum and post-abortum intra-uterine douching and in curetting, and the advantages claimed are: It is simple, light, and cheap. It is a non-conductor of heat, and therefore protects the sensitive perineum. It does not corrode. It can be easily cleaned and rendered aseptic, either by chemicals or boiling. It can be held by an assistant; or, it can be made self-retaining in certain cases. The débris can be seen as it escapes through the trough-handle to the receptacle beneath.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 23, 1895.

	Cases.	Deaths.
Tuberculosis	31	78
Typhoid fever	8	4
Scarlet fever	101	15
Cerebro-spinal meningitis	1	0
Measles	94	9
Diphtheria	189	43
Small-pox	1	0

The Late Dr. Little and the Royal College of Physicians.—It is a curious illustration of the antiquated notions of the London College of Physicians, that for long years the late Dr. Little, the "father of British orthopedy," was passed by in the elections to the Fellowship because he performed operations (for club-foot, etc.). Some of the Fellows indeed loudly asserted that they would always oppose anyone who performed the most trivial surgical operation. And yet the obstetric physicians who perform ovariotomy are welcomed. An evidence of the consistency of the sticklers for the old-fashioned divisions of medicine. In 1877 some of the Fellows woke up to the absurdity of their position in not having among them so eminent a physician whose pupils were of their number. Accordingly Dr. Little was surprised one morning to learn that he had been elected a Fellow. It shows the amiability of the man that, instead of rejecting so belated a compliment, he quietly paid the heavy fees for the empty honor, lest otherwise he might hurt the feelings of any who had taken a lead in the matter.

Defective Color Sense in Asiatics.—Among the publications of the German Asiatic Society of Tokio, Japan, for 1894, is a paper by Dr. F. B. Stephenson, United States Navy, with the title "Color Blindness in Asiatics," giving the result of observations among the natives of Hawaii, Unalaska (Aleutian Islands), Japan, China, Annam, Siam, including the mixed nationalities from Borneo and India who inhabit Singapore and other parts of the peninsula of Malacca. None of these peoples appear free from defective color sense.

Football Casualties.—Under this heading we published an account, in the issue of December 15th, of a student at the Fairfield Seminary who was said to have become violently insane as a result of injuries received at football. A correspondent informs us that the acute insanity was not due to injuries received in the game, but that it was evidently due to over-exertion, a cause which had been effective in exciting the previous attacks.

PECULIAR PERVERSION OF THE COLOR PERCEPTION.[1]

By HOMER E. SMITH, M.D.,

NORWICH, N. Y.

MR. PRESIDENT AND GENTLEMEN OF THE CHENANGO COUNTY MEDICAL SOCIETY: The following case is of more than usual interest, not only from the standpoint of diagnosis, but because it presented one peculiar feature which, so far as I can ascertain, is unique.

H. S——, male, white, aged eleven, of healthy native parentage. Ancestral history good on paternal side, on maternal side paralytic attacks occurring late in life. Eldest of seven children, all others healthy. Had whooping-cough in infancy, and two or three months ago scarlatina, with which there were no, nor have developed later, renal complications. No history of injury. Up to eight days ago, dating from time when history was taken, was perfectly well. Then was noticed slight dragging of feet, absence of usual buoyant step, and an emotional disturbance shown by causeless weeping. Three days later the child said that white surfaces were brown and objects smaller and distorted. At this time the parents noticed inco-ordination in gait (staggering, shooting forward). The child complained of headache (moderate, constant, occipito-frontal). Formication and tingling in arms, fingers, and along the course of the upper dorsal nerves; backache (dull, constant, in lower cervical and upper dorsal regions), and of pain during mastication in temporo-maxillary articulation. There has been no nausea, vomiting, loss of consciousness, or convulsions.

Physical Examination.—Nervous System: Motility unimpaired, limbs placed quickly and correctly in any ordered position. Finger placed instantly on any designated spot. Strength: Hand-grip weaker in right (is right-handed). Co-ordination: Writes as usual and signs his name well with eyes shut. Stands with feet slightly separated, with weight thrown more on left foot, sways slightly, but does not fall when eyes are closed. In walking staggers and shoots forward, but does not fall. Spasm: No muscular twitchings or contractures. Reflexes: Knee-jerk and ankle-clonus abolished. Superficial reflexes preserved. Sensibility: No hyperæsthesia, sensation to contact and pain diminished on both sides, more so on right (leg, trunk, and arm). Subjective sensations as mentioned in history.

The following associating tracts were tested and found to be in perfect working order: The temporo-frontal, occipito-temporal, occipito-temporo-frontal, occipito-central, temporo-central. There is no paresis or paralysis of any of the peripheral nerves. Intellection not disturbed in the least. Special senses, smell, and taste unaffected. Hearing: tuning-fork reactions show B. C. normal for from 128 S. V. to 2,048 S. V. For 128 and 256 S. V., B. C. < A. C. (This, with the slight tinnitus and pain present in both ears, was attributed to local causes.) Hearing good. Vision, O. D. = $\frac{4}{4}$; O. S. = $\frac{6}{6}$. There is no strabismus or conjugate deviation of the eyes. Motion perfect in all directions. Pupils equal and of normal size, contract to light exposure, consensually, to convergence, and to peripheral excitation of the retina (Wernicke's test). Fields, marked peripheral limitation, greater in right. No scotomata. Accommodation not impaired. Selects colors correctly as to shade, but each appears in its complementary, *i.e.*, red is called green, green appears as red. Blue looks like yellow, and yellow, blue. White appears brown. Has micropsia and metamorphopsia. There is moderate photophobia present. Has in each eye monocular polyopia. The ophthalmoscope shows, O. D., diffuse neuro-retinitis. The bulk of the trouble is in the retina, which is œdematous and opaque. The papilla is not swollen but is markedly congested, with a nearly complete obscuration of the choroidal ring. Veins slightly tortuous, no hemorrhages. O. S., same condition, lesser degree. Internal organs: Heart and lungs healthy. Bowels regular. Bladder function not disturbed and urine normal to repeated chemical and microscopical tests. Sleeps well and quietly in usual attitude. Nutrition good. Appetite fair. Tongue slightly coated. Digestion not impaired. Pulse, 64, usual rate about 70. Respirations, 16 to 18. Central temperature normal, with no variations at any time; surface temperature not taken. The child was given three times daily five-grain doses of potassium iodide, which was to be increased by one grain each dose until its constitutional effects became manifest. This treatment, however, was discontinued on account of the rapid improvement, and tonics substituted. For three or four days there was a slight though progressive increase in the symptoms as mentioned in history, and a temporary disturbance of the special senses of smell and taste. This lasted about three days and was of the anæsthetic type. Improvement then began, shown by return of sensation in body and limbs. Co-ordination became re-established. Vision progressively improved. The micropsia and metamorphopsia vanished, and lastly the color sense became normal. At present writing, four weeks from the onset of the disease, there remains only a slight nervousness and a tendency to emotional disturbance.

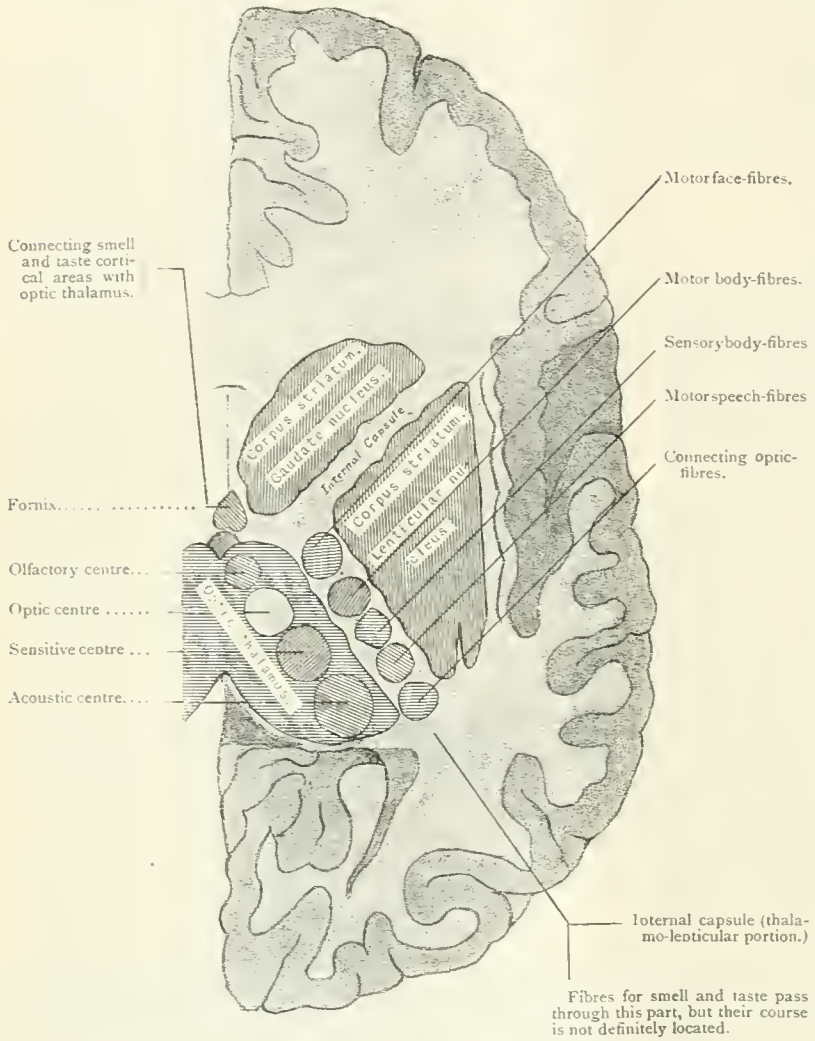
Analysis: The question of diagnosis was to be answered by, 1, the nature of the lesion, and, 2, its location. The first question can only be answered by saying that there was present an intra-cerebral, localized effusion, probably hemorrhagic. The second is thought to admit of a more definite answer.

It is evident, to begin with, that this was not a cortical disturbance. To account for the varied symptoms on this assumption would be to assume extensive lesions over the parietal, temporal, and occipital lobes; these could not occur without grave general disturbance of motion and sensation together with loss of consciousness, with or without convulsions. Moreover, the presence of the optic neuritis, together with impaired motion and sensation on the same side, would point to nuclear disturbance. We must therefore seek for an intra-cerebral lesion, and this was most probably in the left optic thalamus with pressure effects involving the internal capsule in its thalamo-lenticular division.

I have prepared a plate (shown on next page) representing schematically a half section of the brain, at the level of the basal ganglia, which will help to elucidate what I have to advance in support of this diagnosis.

[1] Read by title before the Medical Society of the County of Chenango.

The presence of four isolated ganglia in the optic thalamus is given on the authority of Luys. The separate fibre-bundles in the internal capsule and their functional attributes are in accord with the views of neurologists generally. It can be readily seen how even a circumscribed lesion in this region can give rise to many and varied symptoms. Taking these up in detail and in their order of occurrence, we first had disturbance of the motor and sensory body-fibres. The



Section through Brain, Level of Basal Ganglia. (Right half.)

inco-ordination in gait was more probably a sensory than a motor interference, from the fact that motility was but slightly impaired, and other co-ordinated acts were well performed.

Next in order the irritation of the visual centre, shown by the perversion of the color perception and the resulting neuritis, bringing loss of vision and distortion of objects seen. These latter symptoms will be commented on at length in closing. Lastly, were the olfactory and gustatory fibres of the internal capsule involved, and this involvement manifested by the disturbance of the senses of smell and taste. It is known within how small an area all these centres are practically contiguous, and in this case they seem to have been progressively invaded by the compressing effusion. There is a difference of opinion among neurologists regarding the existence of special sense-centres in the thalamus, but the presence of fibres in the internal capsule which are connected with these senses is practically proven. Hemianopsia, with difficulty in the discrimination of color, sometimes occurs in lesions of the capsule and optic neuritis from pressure thereon.

In commenting on the ocular symptoms there are many points of interest, with much that is negative but which possesses positive value. To begin with, optic neuritis is not a localizing symptom of brain disease. It may simply be the expression of a general dyscrasia, but when bilateral is probably of cerebral origin. The most frequent general causes are syphilis and chronic nephritis. Local causes are cerebral anæmia, cerebro-spinal sclerosis, intra-cranial aneurisms, and, most frequently, intra-cerebral neoplasms. The course and progress of the disease under consideration practically shuts out all these, for while optic neuritis is common to them all, each has its distinguishing features which were absent in this case; moreover, the acuteness of the ocular trouble was presumptive of an acute causation. The condition of the fields precludes the possibility of a cortical lesion; with this in the cuneus or adjacent to the calcarine fissure, we would have had lateral hemianopsia. The peripheral limitations of the field could be accounted for by damage involving the optic commissure, but the pupillary reflex and other symptoms negatived this. The condition of the pupils was of diagnostic value. Responding as they did when light was thrown on the periphery of the retina, where the field was wanting, it showed that the lesion was either back of the communicating fibres of the optic tract to the motor-oculi nucleus, or higher up in the thalamus or internal capsule. Aside from the perversion of the color perception, the visual disturbances may be accounted for by the intra-ocular disease. Micropsia may be due to paralysis of accommodation, but this function was unimpaired. Moreover, the presence of the metamorphopsia showed a disturbance of the retinal elements, for when these are separated by an effusion light rays from an object of given size fall on fewer percipient points, and consequently the object appears smaller; also, if this separation be not uniform a distortion results. The apparent doubling of objects, on being tested, was found to exist separately in each eye, and was undoubtedly an exaggerated distortion. The reduced central vision and the contracted fields are usual accompaniments of neuro-retinitis. There have been cases reported of monocular diplopia or polyopia which were traumatic neuroses, the result of spinal concussion; these have sometimes been accompanied by colored vision. In other cases presenting this group of symptoms, autopsy has shown minute hemorrhages scattered through the brain; chromatopsia or colored vision, *i.e.*, where all objects are seen of one color—for example, as red or yellow—is the result of retinal irritation.

The most remarkable feature in this case, and which makes it of such interest, is the peculiar perversion of the color perception. There is nothing in the literature at my command which bears even indirectly upon it, and the foremost ophthalmologist of this country, to whom the case was submitted, was unfamiliar with it. Hallucinations of the special senses exist, but this cannot be classed as one of them. Paresthesias of these nerves give rise to subjective symptoms with which we are familiar, but in a case like this, as in others of unexplained visual phenomena—for example, where reading is only possible with the book reversed—we must fall back on the "scientific imagination." From the known data of the physiology of vision and the perceptions of color, I can draw no plausible conclusion in explanation of the facts given. There seems, however, to be a reasonable certainty that there exist separate cortical areas for light, form, and color, and probably intra-cere-

bral nuclei for the due ordering and arranging of impressions thereon. May it not be possible that the optic centre of the thalamus presides over the latter function, and that its disturbance was the causal factor in the perverted color-perception herein detailed? There are many isolated unexplained phenomena of cerebration here and there reported, but from which, perhaps, may be drawn, out of seeming confusion, the law which governs them. To put on record a most interesting case, and in the hope that it may contribute somewhat to the formulation of the law, this paper has been written.

ON PLEURITIC EFFUSION, OCCURRING AS A TERMINAL SYMPTOM OF PLEURO-PNEUMONIA.

By BENJAMIN F. WESTBROOK, M.D.,

BROOKLYN, N. Y.

It may be interesting to the practitioners of our art to have presented to them at this season, when the prevalent diseases begin to assume the type of affections of the respiratory organs, a short study of the characteristic features of one of those deviations from their ordinary clinical histories by which familiar diseases are rendered obscure, and through whose occurrence cases which had caused no anxiety to the attendant, at least on the score of their diagnosis, suddenly and without apparent cause develop unexpected and very annoying symptoms.

It is one of the most provoking experiences in a physician's work, and, moreover, an extremely embarrassing one under some circumstances, to have a case of the diagnosis of which there has seemed to be so little doubt that he has perhaps committed himself even to the extent of making a rather confident prognosis, maybe announcing from day to day that everything is proceeding as he had expected, when, of a sudden, his enthusiasm is congealed, his pride humbled, his confidence annihilated by a most extraordinary transformation scene. The entire complexion of the case has changed. Unusual symptoms, the reverse of what he had foretold, present themselves so distinctly that they are unmistakable even by the non-professional eye.

He must make a new observation, revise his opinions, and change his plans of treatment under the eyes of a group of friends whose manner, not improbably, betrays a doubt as to the wonderful skill which they had hitherto attributed to him.

No physician of experience will, I think, call this a fancy sketch. We all know that as remarkable changes as this in the outward manifestations of disease may, and frequently do, occur as perfectly normal sequences, and as phenomena which are indicative of the natural succession of physiological movements in some pathological processes.

A very striking and instructive illustration of this statement is observable in the course of that rarity of pleuro-pneumonia which I shall describe.

It is a variety which I have often seen in the practice of medical friends, but it is apparently of such rarity that in the course of an individual general practice it might not be encountered in years, that is to say, in so pronounced a form as to require special attention.

The sequence of the phenomena is as follows: There is at first an acute pneumonia.

As necessarily occurs, when the inflammation of the pulmonary parenchyma is intense and reaches the surface, the pleura covering the invaded area is also inflamed, and, if the latter process is intense enough to warrant the appellation for the case of pleuro-pneumonia, there will be a friction sound, easily detected at first. But hepatization develops with great rapidity and, as may be readily understood, reduces the gliding movement of the lung on the chest-wall to a minimum, as this movement is dependent on the alternating changes in the shape of the organ caused by its expansion and contraction.

If a large portion of the lung is solidified there is very little motion. Besides, the dryness of the pleural surface which obtains at the onset of the process is soon succeeded by an increased and vitiated secretion which gives only a dull, obtuse sound, more like a nondescript moist râle. The pneumonitis, in these cases, so far as I have observed it, is of a high degree of intensity, and sufficient of itself to absorb the doctor's attention. One result of this is the mechanical condition that the hepatized lung, not at all contractile, does not, and cannot, shrink so as to make place for the accumulation of any pleuritic serous effusion.

When the stage of resolution arrives the absorption of the inflammatory exudate begins. But the tissues of the lung, which have during the inflammatory process lost their elasticity, do not at once regain it. The lung still completely fills its pleural apartment. The resolution is going on, apparently, typically; although, if the physician were to observe very carefully the chest movements, he might notice that during inhalation there is an abnormal sinking of the intercostal spaces, as if something prevented the return of the lung's expansion to the degree corresponding to the apparent amount of reabsorption.

This seems to me to result from the excessive hyperæmia of the subpleural tissues, the unusual gorging of the subpleural lymphatics and those of the peripheral pulmonary zone, to the thick lymph that has collected on the surface, and to an excessive degree of coagulation and granular degeneration of the parenchyma. In very high grades of pneumonitis there is also (I infer *a priori*, although I have not as yet collected the anatomical proof of it) a more extensive and more complete temporary loss of that elasticity of the bronchial walls by virtue of which, and of their radial arrangement, they exert a centripetal traction during inspiration.

As the convalescence seems about to be established, it is noticed that the improvement halts; and presently the patient begins to grow worse, with increasing dyspnœa; a more rapid and a weaker pulse; a failure of the appetite and of the digestive power; debility and returning duskiness of the skin. There is an area of increasing perpendicular depth at the lower part of the chest on the diseased side, where percussion elicits no pulmonary resonance, but only the flat sound obtained by percussing over collections of fluid. The peculiar audible and palpable voice-vibration (vocal fremitus) is, as a rule, absent. "As a rule," because it sometimes happens that a portion of the posterior border of the lung, which has not yet lost its hepatic solidity, transmits, through one or more adjacent vertebræ and along the ribs, a distinct vocal fremitus. This is a fact of the greatest importance in the examination of the chest, for it is one of the commonest of all the stumbling-blocks in the path of physical diagnosis. With infants and young children, in whom the superficial area of the lung is much greater, proportionately, than in older persons, viz., inversely as the cube of the linear dimensions, in whom the posterior border of the lung is displaced less during the respiratory movements, and the transference of mobility to the sound side more readily accomplished, the presence of the vocal vibrations and bronchial breathing in the lower half of the chest, particularly posteriorly, is not in any way acceptable as evidence of lung consolidation, and the error of supposing it to be so is productive of many a mistake in diagnosis.

But to return to our troublesome case. As the lung tissue regains its elasticity, its contractile force, which tends always to diminish its size and to separate the two pleural surfaces, acts, as in health, more strongly during inspiration than expiration. Each time the chest expands the tendency of the pleural surfaces to separate favors the occurrence of an effusion into the

cavity between them. *As a result, we get the pleuritic effusion which, had the hepatized lung not prevented it, would have occurred at the beginning.* As the effusion increases the lung retires from the chest-wall, and eventually we have, replacing the pneumonia, a distinct pleurisy with effusion.

I should say, further, that the temperature, if it had previously declined to the normal degree, rises slightly and remains usually at 100° F. or over for a variable length of time. I cannot make a statement of any value as to the duration of this secondary fever, excepting that, in the absence of complications, it does not endure much, if any, longer than for the period of accumulation, dying away at the completion of that process.

It may be, however, as is well known to clinical observers, that the temperature will be somewhat disturbed while absorption is going on.

The pyrexia noticed during the absorption of pleuritic effusions, usually of a mild though irregular type, is probably due to the entrance of peptones into the blood.

The diagnosis of this condition which I have here described depends simply upon the observation of the foregoing facts, viz.: the occurrence of a pneumonia of, as a rule, more than the average degree of intensity, associated at its onset with the signs of acute pleurisy, which are quite variable, and the most certain of which, the friction sound, is apt to be of short duration and not followed by evidences of serous effusion; râles somewhat like a nondescript mucous râle, fine or coarse, usually both, following the friction, and frequently enduring until the beginning of resolution of the pneumonitis; closely following upon the signs of commencing resolution, a change in the percussion sound, which becomes flat; either absence or presence of the vibratory breath and voice sounds of pneumonic hepatization (vocal fremitus and bronchophony), as coincidences of the change in the percussion signs; at the same time, sinking of the intercostal grooves during inspiration, followed by bulging if the accumulation is large; return of the cyanotic appearance of the skin and mucous membranes, and increasing rapidity with diminishing vigor of the heart-beat.

Later on there may be, of course, other signs and symptoms of pleuritic effusion, such as cardiac displacement, jugular engorgement, cerebral and spinal venous hyperæmia, errors in the distribution and movements of the cerebro-spinal, subarachnoid fluid, portal congestion, and the other items of that long series of disturbances which result from the presence of large quantities of liquid in the pleural cavities, and constitute one of the most interesting chapters in pathology.

I need not occupy the space of our genial editor with a long disquisition on the treatment of the condition to which I have here attempted to call the attention of practitioners, and to elucidate as briefly as was possible.

These deviations from the classical course of well-known and well-understood diseases must, necessarily, be dealt with in accordance with the features presented by individual cases, and as the knowledge of the physician in charge indicates to him. There is one especial point, however, that seems to require a distinct rule of practice.

When it is thought advisable to aspirate, this should be done cautiously, and the suction should be taken off the moment any depression of the intercostal spaces is seen. Otherwise the lung, which has probably not yet entirely regained its normal structure, may be injured, or the cavities of the right heart unduly dilated.

Professor Mauthner, who died on October 20th, had been Professor of Ophthalmology at the University of Vienna just one day. He succeeded the late Professor Stellwag.

SEROUS CAVITIES OR SPACES.

By BYRON ROBINSON,

CHICAGO, ILL.

Serous cavities or spaces are situated in various parts of the body. They have a similar function and are liable to similar diseases. The serous cavities in the order of their size are (*a*) the peritoneum, (*b*) the pleura, (*c*) the arachnoid, (*d*) the pericardium, (*e*) the serous cavities of the joints. Embryologic or natural development shows that serous cavities are all secondary acquisitions. We saw in the progressive growths of the embryo that the peritoneal or serous cavity arose from the mesoderm or middle germ layer. Small clefts or spaces arise in the lateral portions of the developing embryo, and these spaces finally coalesce, forming a more or less differential cavity as regards size and form.

Thus by changes in the mesoderm the peritoneal sac results. The modifications of the middle germ layer are: cleavage, evagination, folding, and coalescence, which lead finally to the structure faced with shining epithelium and backed with beds of areolar tissue—the serous cavity of the abdomen. From invisible clefts in the mesoderm filled with lymph this sac increases until it comes to have about an equal surface with the skin, and will, in the adult, absorb two quarts of fluid per hour. This important membrane is finally intimately and inseparably connected anatomically and physiologically with three great apparatuses—the digestive tract, the genitals (tubes and ovaries and uterus), and the urinary organs.

This cavity is sooner or later lined by a distinct layer of flat, endothelial cells, with here and there present peculiar apertures (stomata) which are lined with what may be called germinal or glandular cells—probably absorbents leading to lymphatic tracts.

The primitive clefts or spaces in the mesoderm are filled with a fluid which resembles lymph, and to all intents and purposes the peritoneal serous cavity may be looked on as a lymphatic sac. It belongs to the lymphatic system. It is not a passive membrane, but an active absorbent, a regulator of circulation. It may be claimed that the serous membranes act as joint-cavities. They give opportunity for motion. The peritoneal cavity I shall view as a joint-cavity, allowing all the movements necessary for the anatomical and physiological existence of itself and its contained functionating viscera. It may be observed that all these serous cavities, like joints, are liable to similar diseases, as inflammations, tuberculosis, etc. The serous cavities are all really closed sacs. The exception of the female in having two apertures for the Fallopian tubes is not an exception in fact, as regards the closure against the passage of serous fluid; for the valvular condition of the mouths of the Fallopian tubes does not allow serous fluids to pass from the peritoneal cavity through the uterus. Hence, practically, all serous cavities may be viewed as closed lymphatic sacs. As closed sacs they become to a certain extent regulators of pressure. This is best seen in the ventricles of the brain. The fluid sacs allow the brain or delicate organs to rest on soft water-beds, protecting them from sudden changes or trauma. The serous sacs act as buffers modifying rude mechanical movements, and distributing forces to safe regions of more resisting structures. The serous cavities with their contained fluids regulate circulation. Observe how in the horse, after vigorously running for several miles, the large dilated veins stand out on his body surface. The fluid in the serous cavities has prevented sudden changes in circulation in the vital nervous centres and the vital viscera. The fluids in the ventricles and arachnoid could not be rapidly displaced, so that the brain under the vigorous pumping of the heart is comparatively safe, for the blood is forced in directions of least resistance—the wide veins and the delicate viscera are spared shock. All these

remarks apply equally well to the lymphatic joint and serous space, known as the peritoneal cavity.

These serous cavities with their contained fluids not only regulate pressure, motion, and circulation, but they are normally always full of fluids or viscera. The fluids and the viscera in the serous sacs alternately play on each other. The fluid plays a double rôle. It facilitates visceral movements with the slightest friction and fills the spaces in the sac due to small changes in the form of the viscera, thus in a certain measure distributing pressure uniformly on all contained viscera. It is in these great serous sacs that anatomy and physiology arise to their supreme significance in the animal economy. In these sacs anatomic structure and delicate visceral arrangement are combined with the most superior design of a physiologic mechanism. The serous cavities are the real physiologic laboratories of life. The anatomic limitation of serous sacs is purely for physiologic purposes. Anatomy and physiology here as elsewhere go hand in hand.

All organs are outside of serous cavities, since they are closed sacs. All viscera lie outside of the peritoneal sac. However, all viscera which have become invaginated into the walls of the serous sacs have certain supports for anatomical limitations and physiological purposes. We will not discuss here whether the supports (mesenteries, ligaments, and omenta) arise as primitive projections of the mesoderm—designed ridges of cellular tissue covered by serous epithelium—for the purpose of transmitting nerves and vessels to the enclosed viscus, or whether the supports are simply duplicatures of peritoneum. As the viscera increase in size in the adult, with the exception of the liver, they project and invaginate further and further into the cavity. The serous membrane gradually wraps itself around the viscus until it is evaginated into the sac, while its pedicle elongates. All supports (ligaments, omenta, and mesenteries) of viscera in the peritoneal cavity are the same. They consist of a double layer of peritoneal membrane. These visceral supports are not merely to anchor the organs to the wall of the abdominal cavity, but they convey vessels and nerves for the demand and supply of the organs. They are neurovascular pedicles. Fixation belongs to few abdominal organs. The liberal lengths given to the supports of viscera permit them to perform their rhythmical functions. Every viscus seems to me to have its rhythm. Rhythmical organs require space for their delicate motion, as well as for their contraction and expansion. It may be observed in the abdominal serous cavity that nerves and blood-vessels are systematically grouped, indicating an original division of the digestive tract into its three great regions—stomach, small and large bowels. The supports of the abdominal viscera vary at different times of life, and I have found by careful examinations of fœtuses that scarcely any of the original mesenteric supports exist in the adult; even the mesentery of the descending colon, which I had long thought was the original mesentery, first disappears about the sixth month of fœtal life and rarely appears again, only the sigmoid mesentery represents the original. In the serous cavity of the peritoneum there are two kinds of serous membrane, which may or may not differ in structure and function. One portion of the great sac is intimately in contact with the viscera and is named visceral layer (serosa visceralis). The other portion of the peritoneum is called the parietal layer (serosa parietalis). An important factor in the peritoneum is its subserous strata. The amount of subserous tissue not only varies in thickness, but varies in localities. The peritoneal substratum on the anterior abdominal wall is very small, but the areolar tissue is abundant toward the pelvis and in the dorsal region. It is very important to be familiar with the thick beds of white, snow-like areolar tissue that underlie the serous sac. The practical application of this anatomical fact applies to hernia, the bladder, and the uterus. It is well to observe the fact in operation on the colon and kidney, which organs can be attacked from behind. Many of the organs connected with the peritoneum are sufficiently uncovered to allow surgical procedures from behind. The excessive beds and layers of areolar tissue immediately under the peritoneum endow the peritoneal membrane with wide mobility. The membrane can move easily on its bed, it can pucker and dimple and pouch, by which process it solicits hernial projections. It is probably owing to this yielding bed of areolar tissue that visceral supports elongate (prolapse) with age. I have observed that in all fœtuses and young human subjects the visceral supports are short and the viscera are high in position, but with increasing senility the visceral supports elongate and the organs prolapse. Visceral supports are not for the purpose of preventing hernia through the contained walls, but for the purpose of allowing visceral rhythm and to prevent the organs from becoming entangled. The organs are so anchored that they seldom strangle each other by knots, twisting, or pressure. In the lower animals the digestive canal is very long and convoluted, the peritoneum is more liberal than it is in man, but the visceral supports maintain absolute order among the various organs.

A serous cavity, in general, has an important function in animal life. In viewing it as a joint we compare all movements. It comprehends also all means by which the joint maintains its existence and accomplishes its end. A smooth surface and a lubricating fluid are the essentials for motion. This peritoneal joint, or serous cavity, however, not only accommodates itself to bodily movements, but it adapts itself to functionating contents. It is a depository of changing and moving organs which subserve the object of digestion, gestation and urination, and rhythmical organs. The joint must adapt itself to viscera which have enormous changes in volume. Its walls and contents are in exquisite harmony by being supplied with branches of the same nerve-trunks.

The wisdom of having three serous cavities distinctly divided by strong partitions, though in close proximity, is apparent when one contemplates the spread of inflammatory conflagrations as well as the utility to function and physical protection by confinement. The anatomic and physiologic properties of a serous cavity and its contents present all the known perfections of the most exquisite mechanism. The slimy epithelium of the serous membrane lies on the top of deep beds of snow-white areolar tissue, which possesses properties of elasticity and yieldibility, contraction and expansion, without loss of integrity. The contained organs of the serous cavity possess mobility without dislocation. They have the power to change their form and return to normal without losing their integrity. The organs are endowed with rhythm, elastic and muscular tissue, and varied function. The serous membrane, peritoneum, which lines the walls of the serous cavity and covers the organs evaginated into its fold, in varying degrees, not only facilitates all movements, but it regulates to a certain degree ovulation, digestion, and circulation.

The serous membranes are so named from the appearance of the nature fluid they contain — serum. The peritoneal cavity is always full. No empty space exists in the cavity. Abdominal pressure, which is muscular tension, forces the walls and viscera in intimate contact. Atmospheric pressure aids in excluding any open spaces in the peritoneal cavity. There being no empty spaces in the peritoneal cavity, the pressure inside and outside of a gut will be just the same, and this principle explains why the bowel contents do not flow out more readily into the peritoneal cavity, when a gut-wall is perforated or torn. The peritoneum is so thin that one can scarcely feel four layers between the finger and thumb. It is transparent,

and its endothelia are flat and irregular in outline and studded here and there with stomata, whose mouths are surrounded with a ring of small cubical cells. These little mouths open into sub-adjacent lymphatic channels. The blood-vessels of the peritoneum end in a capillary net-work which especially pervades the subserous tissue. The blood-vessels are much more numerous near parts of the membrane where lymphatic tissue exists.

A CASE OF LUMBAR HERNIA.

By C. M. GALLOWAY, M.D.,

XENIA, O.

W. M. R—— enlisted in the Union Army on August 3, 1862, and was discharged June 9, 1865. He was a sound man physically when he enlisted. A short time after he enlisted, while on a march, his belt, which held in position his cartridge-box, cap-box, and bayonet scabbard, became twisted (because it was made of flanky leather) and caused the shank of his bayonet to rub on his left side, at the exact spot where the hernia

is now located. Soon afterward he began suffering from a severe pain in his spine, from the coccyx to the base of the brain. From that time until the date of his discharge he was able to perform light duty only. When discharged the hernia was about the size of a partridge's egg and has gradually grown to its present dimensions—five inches in length by two inches in width. About twelve years ago incontinence of urine began and is yet present, due to the presence of spinal irritation, the medical examiners say.

During the past year an abdominal hernia over the region of the stomach has made its appearance, for the relief of which he wears a truss. The man has a peculiar nervous symptom, which he states is of recent origin. When walking along the street he will unwillingly turn and walk in the opposite direction, and continue until he grasps some stationary object, and stop himself, when he can turn around and continue his walk in the original direction. At such times he feels strange, but has no unusual pain. The lumbar tumor requires now a pad five inches in diameter to hold it in place. The patient is much emaciated and weighs one hundred and twenty pounds. The accompanying illustration shows location and size of the hernia.

THE USE OF THE BICYCLE FROM A PROFESSIONAL STANDPOINT.

By JOHN B. RICHARDSON, M.D.,

LOUISVILLE, KY.

After employing a horse and buggy, in the practice of my profession, over the streets of our city for more than twenty-two years, I found I was not getting sufficient physical exercise to prevent frequent attacks of headache and sleeplessness, and was becoming quite too corpulent for comfort. I determined to give them up and try walking. I very soon regained perfect health, but was convinced walking was too slow for long-distance visits. The use of the bicycle was the alternative, which, at that time—nearly four years ago—was considered here a great innovation, deemed, to say the least, a rather undignified or puerile species of locomotion, entirely devoid of practical utility, and its employment requiring a more than minimum degree of temerity, especially in a professional man. Possibly I was a little advanced in years to adopt such a novelty, as I had then nearly reached the shady side of the half-century mark. Nothing daunted, I strode my Pegasus, and found him, at first, rather unruly and difficult to manage, almost equalling "in ways that are dark" and unexpected positions and locations the proverbial mule, when first saddled and bridled.

After, however, a few four-A.M. (to escape observation and unfavorable criticisms) excursions over asphalt pavements, I mastered the wonderful steed, and now feel as much at ease on his back as when seated in my easy-chair in my study.

There are some rules by which riders should be governed, and in accordance with which they should act, if they wish to derive all the benefits and not fall heirs to any of the evil results of "cycling."

A perfectly fitted saddle and the proper position of the saddle stand first, being of major importance.

When seated upon the saddle, placed at the proper angle for the rider, his weight should rest upon the gluteal muscles (except what is impinging upon the pedals), and under no circumstances or at any time should any weight or pressure be permitted to fall upon the perineum, for just this and this alone (excepting falls from the machine) is the cause of most all of the cases of irritation and inflammation of the neck of the bladder, of the urethra and prostate gland, and abscesses which result from bicycle-riding. My advice to dealers in bicycles is, never allow the use of an ill-fitted saddle; do not weary of making changes in the saddles, or altering the angles at which they are placed and secured, until their proper adaptation has been perfectly accomplished, for in this lies the secret as to whether or not the use of the bicycle shall result in benefit or harm to the rider.

Where there is already existing disease of the genito-urinary organs, or local irritation from any cause, the use of the bicycle is contra-indicated. Given, however, a perfectly sound person in this regard, its use within reasonable bounds will redound to his benefit and not to his injury.

The most natural, healthful, and graceful position for horseback-riding is the erect posture, with the stirrup-straps of such length as will allow the rider's legs to be almost fully extended, permitting him to bear most of his weight upon the balls of his feet on the stirrups. So, after one has learned to ride the bicycle, the saddle should be so elevated that, the rider's leg being ex-

tended, the down pedal will be sufficiently low to enable him to touch it easily with the heel of his boot, thus keeping most of his weight upon his feet, and lessening the proportion of weight upon his gluteal muscles.

The rider's body being perfectly poised in the erect posture places his lungs and heart in their best possible relative position to carry on their functions, and not impede the circulation through the heart and vessels, and by pressure of contiguous parts preventing the free expansion and contraction of the air-cells, as is unavoidably done in the leaning-forward position, the latter being unnatural, ungraceful, and unphysiological, as well as invariably injurious.

A safe rule, to which there can be no exception in the use of the bicycle, and which with equal force is applicable to all other forms of exercise, is: Exercise short of fatigue. This observed, one will obviate the necessity for the obedience of a second, viz.: Rest frequently.

Excessive exercise here, as along every other line, is injurious, and is to be eschewed. With greater force does this apply to the young, growing, or physically undeveloped rider. Even in hill-climbing or rapid riding the erect posture should be assumed and maintained.

Most professional riders insist that the forward-leaning, partially-closed-"Jack-knife" position is essential to rapid riding, and many youthful riders assume it, as it smacks of the professional, to their temporary and at times permanent injury. If this be true, it cannot apply to health-seeking or pleasure-riding. Again, the assumption and retention of this position is a frequent cause of perineal troubles, bringing to bear a great amount of pressure upon those parts which should never be pressed upon, and which even the most perfectly fitted saddle cannot, in that position, be made to prevent.

Racing, either competitive or against time, is generally injurious, unless the rider has been gradually brought to that degree of muscular development through months of careful training. Riding long distances at a rapid rate of speed can only eventuate in harm, resulting in hypertrophy of the heart and its consequent dilatation, or overstraining of other muscles or sets of muscles. Gentle exercise upon the bicycle in every healthy person, after becoming inured to its use, produces a wonderful exuberance of spirit, which if not checked will create the desire to "speed." This can be controlled if taken in the initial, but will grow upon the rider if he is not continually on the *qui vive* to hold it in check, and should not be indulged in by the health-seeker or the young. The subject of respiring during the use of the bicycle is one of importance. My experience in hill-climbing, or in rapid riding on the level even, is that one is forced to use mouth-breathing; but in riding on the level it is better to breathe through the nose, especially in cold weather, for it is a well-known fact that atmospherical air, after passing through the nostrils, upon reaching the air-cells of the lungs is some degrees warmer than when it passes through the mouth upon reaching the same point. Bicycle-riding causes free lung-expansion, thus dilating air-cells which during the more common forms of exercise remain quiescent, partially collapsed, and unemployed, their distention keeping them in a physiological condition causing their healthy action, and retaining them in that state in which it is most desirable to have them in both health and sickness.

Bicycling develops the general muscular system, and is not confined, as some suppose, to the muscles of the lower extremities. This will be corroborated by all wheelmen. Those of the back, chest, neck, abdomen, and also of the upper extremities are brought into constant use in the earlier essays at riding, in getting on and off, and in balancing and guiding the wheel. All of these sets of muscles are constantly employed in hill-climbing, and can be exercised by the expert rider when he so desires, even if it be not essential on a level road.

Use but do not abuse the use of the bicycle. I am persuaded by experience and observation that ill results are generally attributable to carelessness in some one or more respects, to overuse, or to too long or too rapid jauntings; for there is no form of exercise more vivifying, exhilarating, or health-giving than excursions leisurely made, with agreeable companions, in pleasant weather, over the hills and dales of our own God-blessed "Blue-grass Country."

A very wise and observant old Friend—a layman—remarked to me many years since: "Antidote for indigestion, eat less. For nervousness, exercise in the open air and sunshine." His conclusions were axiomatic.

I have prescribed for many sufferers from the above-mentioned ills the use of the bicycle, and have lost them as patients, the benefit in some instances being immediate, as well as in some chronic cases of headache, constipation, etc.

As a vehicle of convenience one has only to employ it for a short time to appreciate it.

It requires no great physical effort to traverse a mile over level, smooth pavements in from six to eight minutes, and this rate is not wearisome.

I have on a number of occasions arisen at midnight, dressed, and ridden on my wheel to a patient's residence, and arrived there before the messenger did. It is not only a time-saver, but a saver of suffering ofttimes: always ready, night and day; requires no feeding or grooming; is never sick unless its rider is, and soon becomes to its owner a thing of beauty, for which he forms a true attachment.

Where one has any local disease, and is in doubt as to the advisability of his using a bicycle, he should consult his medical adviser prior to deciding.

I have found marked benefit accrue from its employment, it being a provoker to exercise, in those who are disinclined in that direction, as after learning to manage it with ease the necessary physical labor requisite to run it is so slight that many enjoy it who are too indolent to walk or ride horseback. It is a very rapid form of transit, and gives one change of scenery he may have never before known.

I have seen consumptives well progressed in their disease benefited by its gentle and prudent use: their appetites increased, digestive and assimilative powers enhanced, their sleep prolonged and made more refreshing. Its use is an excellent and effective promoter of the skin's action, stimulating the sweat-glands to gentle but emphasized activity. On the latter account riders cannot use too great care against the catching of colds.

In many diseased conditions this activity of the sweat-glands is greatly to be desired, and can be taken advantage of by the physician. The mere suggestion is only necessary.

Where the building-up process is a desideratum, and no contra-indication obtains, gentle exercise on the bicycle will be found of great benefit. It is far preferable to the exhibition of medicaments whose object is to stimulate and tone up the action of the heart, stomach, lungs, skin, and intestinal canal. It gives more of God's medicine (oxygen, sunlight, physical and mental exercise and diversion, self-forgetfulness, etc.) and requires less of the doctor's. To sum up: Rapid riding, or riding long distances at a rapid rate, is injurious in many ways to every rider, unless gradual and careful training has been gone through with that object. Gentle and moderate bicycle-riding increases vitality; improves and enlarges lung and breathing capacity; develops the muscular (general) as well as special systems or sets, as also the heart's power; increases appetite and powers of digestion and assimilation, thereby adding to capacity for life and increased longevity; stimulates action of skin, and thereby elimi-

nates more rapidly and perfectly effete materials from the system, thus aiding the kidneys when they are temporarily unable to perform their functions perfectly, or are organically diseased; is an excellent means for mental and physical diversion; causes many indolent persons and those who lead sedentary lives to exercise more freely, being pleasurable and easy to take after mastering the machine; is one of our best simple measures in the treatment of cases of insomnia, and, last but not least, is an agent in the moral culture of individuals in pleasurably diverting their minds and meeting their demands for occupation, thus answering the place of saloons, beer-gardens, and other similar places, where companionship is sought.

CASE REPORT OF FIBROID TUMOR OF THE UTERUS WITH SUPPURATING OVARY DISCHARGING PER RECTUM.[1]

By RUFUS B. HALL, M.D.,

CINCINNATI, O.,

PROFESSOR OF CLINICAL GYNECOLOGY AT THE MIAMI MEDICAL COLLEGE; GYNECOLOGIST AT THE PRESBYTERIAN HOSPITAL; FELLOW OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS; OF THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION, AND THE BRITISH GYNECOLOGICAL ASSOCIATION.

Mr. President and Gentlemen: The subject of operative treatment for fibroid tumors of the uterus is one in which the keenest interest is manifested by men engaged in abdominal surgery. The main points in the technique of the operation have been practically settled, but certain minor details in operative procedure are capable of improvement. The greatest difficulty is to successfully overcome certain complications and obstacles occasionally arising, which tax to the utmost the skill of the operator.

The following case, which I shall report somewhat in detail, illustrates a number of these complications, and will serve as a basis for a few remarks to be made later.

Mrs. J. W——, aged forty-four, married sixteen years, mother of five children, the youngest six years of age, was referred by Dr. Heady, of Glendale, O. She always enjoyed good health until about five years ago, at which time she observed that the menstrual period was prolonged and somewhat excessive. As time passed on she noticed that this symptom grew worse, and within a year or two was added pain in the back and a heavy bearing-down sensation in the pelvis during and for a few days following the menstrual period. She did not apply to a physician for relief, however, until some time in February of the present year, when the diagnosis of fibroid tumor of the uterus was made, and the usual treatment followed by the general practitioner suggested. This had little effect, either for relief of the hemorrhage or of the pain, which had become quite severe, especially in the right side of the pelvis and abdomen.

She gradually grew worse until the latter part of April, when she was confined to bed with an attack of general peritonitis. She was very ill and had a high temperature and rapid pulse for two weeks. She then had a discharge of several ounces of pus per rectum, which relieved her somewhat of the pain, and the temperature dropped for a few days. Her general symptoms were not at all improved, but were really aggravated. The temperature chart and her general condition showed her to be suffering from sepsis. There were soon added diarrhœa, chills, and sweats. In the course of eight or ten days she again had a discharge of several ounces of pus per rectum, and was again temporarily relieved. This periodical discharge of bad-smelling pus continued at irregular intervals up to the time she entered the Presbyterian Hospital in my service, June 2, 1894, when the case was first seen by me.

The patient was fairly well nourished; pulse, 140; temperature, 103. She was unable to walk or sit up, and had to be carried into the institution. She was having diarrhœa, irregular chills, and profuse sweats, which she said had been of almost daily occurrence since the abscess first discharged. There were intervals of eight or ten days in which there was no discharge of pus; the diarrhœa and sweats were always worse at that time. The patient said there had been no discharge for more than a week before she entered the hospital, and expressed a wish that it would soon discharge again so that she might have relief.

Examination revealed a hard round tumor in the abdomen, apparently the size of a cocoanut, extending some four or five inches above the symphisis pubis, and slightly to the left side. By combined examination, this tumor was diagnosed as the fibroid uterus. Behind and to the right of the tumor, filling up the pelvic cavity and projecting well toward the perineum, was an elastic tumor somewhat larger than the fibroid just described. This latter I believed to be a suppurating ovary, and from the clinical history had every reason to believe there was a communication with the bowel through which it emptied out a small part of its fluid contents.

The patient was in such a wretched condition to be subjected to a section that an operation seemed to promise but very little. Her friends and physician, who had assumed charge of the case but a day or two before she entered the hospital, were very anxious for the operation, knowing full well that without it she had absolutely no chance for recovery. She was able to take but little nourishment, and that of the blandest character, owing to the irritability of the stomach.

On June 6th the operation was made and the tumor removed. I here present it for your inspection, as it will aid very materially in the explanations to follow. You will observe that the solid part of this tumor is the fibroid uterus, including the neck and cervix. As is my custom in these cases, I made total extirpation. At the side of this tumor there is a sac which represents the suppurating ovary; it is densely adherent to the fibroid uterus. You will see on the lower part of the sac an irregular opening through which you can introduce the thumb. This is the site of communication with the bowel, and will be described later. The opening into the sac near the fundus of the uterus is the point of rupture of the sac during extirpation, after the occurrence of which it was hastily torn open so as to facilitate washing it out before enucleation. The fibroid tumor rode up out of the pelvis proper and rested upon the sac of the suppurating ovary, which practically filled the pelvic cavity and was universally adherent. The omentum and intestine were adherent over the top of the tumor, closing in every portion of it, as you will observe upon careful examination of the specimen. The adhesions were overcome with considerable difficulty. They were all separated down to near the point of attachment to the bowel at the point of communication. When we neared that point, we separated as much as possible of the capsule of the suppurating ovary around the opening, leaving several tags of the capsule attached to the bowel, hoping that thus we might separate the sac from the bowel without making a communication with it, there having been no discharge of pus from the bowel for ten or eleven days. In this, however, we were disappointed, for when we had enucleated the sac, we could pass two fingers into a rent in the bowel, which proved to be the rectum just below the promontory of the sacrum. A resection or Murphy button was out of the question. The opening was immediately plugged with gauze and the operation of total extirpation proceeded with.

When we had completed total extirpation, we could say with all candor that nothing in the pelvis remained

[1] A paper read at the Southern Surgical and Gynecological Association, Charleston, S. C., November 13, 14, and 15, 1894.

which had the least resemblance to peritoneum. For that reason no attempt was made to close the vagina from the peritoneal cavity with stitches, as is my custom, but the vagina was packed with gauze and our attention turned to the repair of the hole in the rectum. This opening crossed the rectum diagonally, and by experimenting we found we could bring the edges together without materially lessening the calibre of the rectum. With a fine suture of catgut, a running stitch was made of the mucous membrane only. After this the muscular coat was brought together with interrupted silk sutures, and on top of this, one of the tags which had been peeled from the outside of the cyst wall, and which was still adherent to the bowel near the opening, was turned over the row of stitches and united around its free margin with twelve or fifteen interrupted silk sutures. The cavity was thoroughly irrigated, the pelvis packed with gauze, and the wound closed. Before the patient was put to bed, the sphincter ani muscle was thoroughly dilated.

The operation consumed one hour and five minutes time. The patient was put to bed in profound collapse, but she rallied within a few hours and appeared to be none the worse for the severe ordeal through which she had passed. The gauze in the pelvis was removed through the abdominal incision on the fourth day, and the pelvic cavity washed out with peroxide of hydrogen, there being a free outlet through the vagina. This washing out process was repeated every four to six hours for ten or twelve days. There was never the least indication of leakage through the bowel injury.

For nearly three weeks the high temperature, rapid pulse, and sweats continued, though not so severe as before the operation. At the end of that time her temperature became normal and she improved rapidly. She left the hospital the middle of the fifth week, thoroughly convalescent, and is now perfectly well.

There are a number of questions of operative procedure suggested by this case, to which I wish to direct attention. Whether or not to advise an operation upon a patient suffering from prolonged and profound sepsis, during the attack, or wait with the hope of putting the patient in a better physical condition, is a question that must be decided on the merits of each individual case. It is a question that admits of discussion both pro and con. There are good grounds for basing an argument on either side, but there are cases where there is nothing left to do that promises any chance of saving life except the radical operation.

The technique of the operation for fibroid tumor associated with a large suppurating ovary, is an interesting study. If with extensive raw surfaces in the pelvic cavity which have been thoroughly bathed in pus during the operation, and no peritoneum to close off these raw surfaces from the general peritoneal cavity, we use the Baer method, which does not give thorough drainage, I do not believe we will have such satisfactory results. I think total extirpation of the cervix, leaving free communication into the vagina for subsequent drainage, gives the ideal condition, both theoretically and practically, for after-treatment in this class of cases. I can unhesitatingly recommend it.

The separation of the firm adhesions of the bowel in the pelvic cavity should be done with the utmost care, for even then a bowel injury is not uncommon. In cases where there has existed communication for several weeks or months, we necessarily have a bowel rent in a very unsatisfactory condition for repair. If there is no peritoneum to be recognized as such for some inches from the injury, and a resection or Murphy button is out of the question, the strengthening of the suture line with a tag of adventitious tissue, as described in the operation, is very desirable. It is a method I have employed on several occasions with perfect results.

Packing the pelvic cavity with gauze, thus keeping the healthy intestine away from the raw surfaces in the pelvis, and protecting the general peritoneal cavity from intestinal leakage, if any should occur, preventing intestinal adhesions there, is a step in advance in the treatment of these cases and one to be commended. It cannot be fully appreciated by those who have not employed it. I usually remove the gauze in the pelvis on the fourth day and wash out the cavity with peroxide of hydrogen, repeating this washing out four or five times daily as long as necessary.

Again, forcible dilatation of the sphincter ani muscle before putting the patient to bed, adds greatly to the chances for recovery. It causes incontinence, thus relieving the intra-intestinal pressure from accumulating gases. All of us who have had experience in abdominal work, know that the sphincter muscle in these cases contracts to such a marked degree that the large bowel frequently becomes enormously distended with gas; and if there is a rent, it puts undue pressure on the weak point, thus favoring intestinal leakage into the peritoneal cavity. So far as I know, I was the first man to practise forcible dilatation for this purpose. The first time I employed it was February 6, 1893, in a case of extensive bowel injury, in a patient operated upon for extra-uterine pregnancy. The patient recovered.

CONTREXEVILLE.

By DEBOUT D'ESTRÉES, M.D.,

PARIS, FRANCE.

A KNOWLEDGE of the virtues of Contrexeville, the springs of which were till then only visited by the inhabitants of the neighboring villages, dates from the lecture read before the Société des Sciences et Arts of Nancy, January 10, 1760, by Dr. Bagard, first physician to King Stanislas, of Lorraine, to whom we are indebted for the following passage:

"The mineral waters of Contrexeville are a sovereign remedy in diseases of the kidneys, of the ureter, of the bladder, and the urethra, stone, gravel, glaires, suppuration. We can assert that these waters are efficacious against the stone, which they loosen and drive out of the bladder, when the stone is not of a considerable size; that they dissolve and break larger stones when the latter are chalky. We keep a list of patients of all ages who during several years have got rid of stones through the effect of these waters. They prevent fresh attacks of gout, by restoring the suppleness of the nerves and of the membranous parts which the disease has dried up. As these waters contain ferruginous matter, a mineral acid, and soap, they will be very useful in cases where the bile becomes too thick and where the liver is obstructed, the more so as these waters are purgative."

This quotation gives, in the medical style of the period, a very exact idea of the properties of the waters of Contrexeville, which it exaggerates in nothing. And from this time foreign invalids began to make use of them.

Many very celebrated cures are still authentic, and among others that of the Abbé de Bouville, who, after having been three times operated on for stone found relief for his pains at this spring, and was enabled to finish his career, which was prolonged for many years, without again having to undergo an operation.

Effects quite as remarkable, observed in the persons of many noblemen of Lorraine and its environs, began to make a great reputation for the waters.

From 1775 to 1789, thanks to the renown and merit of Thouvenel, physician to the Court at Versailles, who was loud in the praise of the waters, the village of Contrexeville saw princes and gentlemen thronging to its establishment. These personages, in their moments of leisure, amused themselves playing tragedies and comedies in the pretty little theatre built by the Prince d'Hennin at his own expense.

The English visitors at Contrexeville built, in the year 1783, a mansion known as the "Château des Anglais," which is now only inhabited by some of the poor workmen of the place.

One can easily understand, after what I have just said, the terrible shock the Revolution of 1789 must have been to the fortunes of Contrexeville, which the minister Necker wanted to buy for the state. Emigration deprived the village of the yearly presence of its noble visitors, and as long as the troubles of the Revolution lasted the station was almost deserted.

At the time of the Restoration a late surgeon of the Imperial army, Mamelet, came and settled at Contrexeville to practise medicine. He had occasion to meet there Dr. Thouvenel, who made known to him the properties of the spring of mineral waters. In 1825 Mamelet, who had conscientiously studied the effects of these waters, published a work, which made such a sensation that from that time forward they took an important place in therapeutics. M. le Dr. Civiale, wrote, in 1828: "It seems evident to me that these waters possess the property of strongly exciting the urinary organs, and that this property renders them useful for determining the expulsion of large gravel, at the same time that they lead to a surer diagnosis of stone in the bladder, a question which is of more importance than one thinks."

Between 1825 and 1844 Mamelet published a second, and then a third edition of his work. Nevertheless, the affluence, so considerable to-day, was slow to establish itself at Contrexeville, in spite of the incontestable merits of this station.

M. le Dr. Peshier, member of the Academy of Medicine of Paris, in his report on Mineral Waters (March, 1853), thus explains the reasons of this: "While our numerous thermal establishments, so various, but all animated with a desire to make a noise in the world, sounded their own praises in advertisements as well as by the results of study and scientific discussion, Contrexeville alone, scarcely drawn out of its obscurity by the conscientious, though not well-known works of Bagard and of Thouvenel, waited in silence for the gratitude of its clients to lead medical opinion to determine its precise value. Innocent of all surprise of stimulating general opinion, disdaining a precocious discovery which might end in myth, this bountiful spring, by the simple fact of the multiplicity and the constancy of the cures, which were made known all over the world, arrived at such a point of notoriety that its name is not less identified with the idea of gravel than that of sulphate of quinine is with the idea of intermittent fever. This justice is rendered to it everywhere and without contest."

Contrexeville is situated in the Vosges, in a valley open from south to north. One meets in every part of this valley, at a depth of about three yards, a layer of green clay about a yard thick, through which the spring "Pavillon" has made its passage.

The cistern for arresting the water which penetrates this green clay isolates the spring from rain-water, which circulates in the calcareous beds above this layer of clay, and thus permits the water to arrive free of any admixture to the surface.

Source du Pavillon.—This water is cold and limpid; its temperature is invariably 11.5° Centigrade. Its specific gravity does not exceed 1.025. It has a slight ferruginous taste and is very refreshing. It produces scarcely any effect on litmus paper, but it gives a greenish color to sirup of violets. When exposed to the open air, it is soon covered with an iridescent film, which disappears when the water is shaken. The stone reservoir into which it falls, the pipes through which it passes, whatever is thrown into it, are rapidly covered with a yellowish coating resembling rust, which is composed of carbonate of iron mixed with carbonate of lime.

The principal minerals the water contains are, according to the analysis made in 1864 by M. Debray, sulphates of lime and of magnesia, bicarbonates of lime and of magnesia, of iron and of lithium, to which we must add traces of fluoride and of arsenic.

It is, therefore, above all, a water having a foundation of lime with lithium, to which iron and arsenic add their reconstituting qualities, so precious for our anæmic generation. This spring is also slightly laxative. These properties render it useful for patients whose sluggish intestines have to be stimulated.

Manner of Employing the Waters.—It is evidently to the ingestion of the water that the good results obtained at Contrexeville are due. Taken fasting, a glass at a time at intervals of ten, fifteen, twenty, or thirty minutes, it produces on the human economy effects which we shall describe further on. It is, to quote Dr. Patissier, "so friendly to the stomach" that it can be taken in relatively large doses. These doses must, nevertheless, be regulated by a medical man, according to the age, the sex, and the disease of the drinker.

A robust man suffering from gravel, a debilitated gouty patient, a woman suffering from hepatic colic, an old man suffering from catarrh of the bladder, would each require a different and special treatment.

In most cases the results obtained by treatment at the spring itself, are confirmed by the use of the water at home. Its effects, inferior to those at the spring, are, nevertheless, easy to prove by those who have used them, especially in cases of chronic affection of the bladder.

It is important, however, that the water should be drunk, as a rule, fasting or during the intervals between meals. Finally, although we have known a case where satisfactory results were obtained with water which had been bottled for seven years, we recommend patients to procure for themselves the water, as fresh as possible, by applying either to the establishment at Contrexeville, Vosges, or to any mineral-water dealer in the United States.

Physiological Effects.—The waters of Contrexeville stimulate all the secretions, but they especially help that of urine. In the digestive organs this stimulation is at once observed to act upon the stomach by increasing the appetite and regulating the functions of the digestive organs. This is especially remarkable in patients suffering from those dyspeptic ailments, which so often precede the appearance of the uric acid diathesis.

The waters are also observed to act on the intestines by producing a laxative effect, shown by two or three liquid stools, which does not in any way fatigue the patient.

In the circulatory system the stimulation of the waters often causes a kind of inebriation of the patient, which always disappears after the first meal. The functions of the skin are restored by the influence of the hydro-mineral treatment when they have been suppressed. According to Dr. Baud, the genital organs of men are also stimulated by the use of the waters of the Pavillon. On women suffering from gout or gravel, it tends to the regulation of the menses, and thus has rendered fruitful gouty women who until then had been barren.

But it is upon the urinary system that the principal physiological effects are produced by the waters of Contrexeville. They produce considerable diuresis, and the quantity of liquid voided is always greater than the amount of water which has been absorbed. They modify the mucous membrane of the urinary tract, and the remarkable results in catarrh of the bladder are due to this effect. They stimulate atony of the bladder. They drive away the pains caused by gravel in the kidneys, as can be seen every day at the spring of the Pavillon, and they expel the excess of uric acid from the system. Finally, they often reveal the presence of large calculi, unsuspected till then, and the size of which will not permit them to pass through the natural channels.

The diseases treated at Contrexeville, are, in the order of their frequency, as follows: Gravel, gout, diseases of the bladder and of the prostate, diabetes, and hepatic colic.

Gravel.—The effects obtained at Contrexeville in cases of gravel are too universally known for it to be necessary for me to dwell long on this subject; the brilliant results which caused it to be said that Contrexeville was for gravel what sulphate of quinine was for intermittent fever, would be still more remarkable if all the gravel patients would keep the health rules so strongly recommended to them when they leave Contrexeville.

Unfortunately, a great number of them break out into excess by either indulging in a too rich diet or by leading a too sedentary or too busy life, and the same causes bring back the same effects, and they are obliged to come to the spring of the Pavillon to be able to indulge again in excesses.

This applies specially to uric acid gravel (red gravel). M. Durand-Fardel, inspector of the springs of Hauterive at Vichy, whose works on mineral waters and on chronic diseases have a legitimate authority, classes, in the following manner, the use of the waters of Contrexeville, for this kind of gravel:

"In cases of renal pains, when the reappearance of nephritic colic is to be feared, or in less simple cases where continual pain or turbid urine reveals a certain degree of inflammation or of catarrh in the region of the kidneys, the waters of Contrexeville—imported if necessary, but especially to be taken on the spot—are clearly indicated.

Bicarbonated and strong mineral waters, especially those of Vichy, are, on the contrary, to be avoided in such cases. We must insist upon this point, which is not sufficiently known to the majority of medical practitioners."[1]

In cases of phosphatic gravel (white gravel) nothing has given results to be compared to those obtained at Contrexeville.

The urine of patients suffering from this affection is either strongly alkaline or less acid than normal urine, and the patients see for themselves this phenomenon, at least surprising, that under the influence of the use of the water, slightly alkaline, of the spring of the Pavillon, their urine becomes more or less acid.

This is simply caused by the fact that the inflammation of their urinary channels disappears under the treatment, and the urine is restored little by little to its normal condition.

When gravel exists it is often passed out in small pieces, for this is far from having the consistency of uric acid gravel.

Gout, and more particularly atonic gout, is one of the affections which is most benefited by these waters. If anyone doubted the consanguinity of gravel and of gout, a season at Contrexeville would very soon undeceive him. It is, above all, a place for gouty patients suffering from gravel, and of patients with gravel suffering from gout.

Under the influence of the treatment the attacks of gout first become less acute and frequent, and then completely disappear, coming back again when the patient forgets the laws of hygiene.

Some of our patients, whose detailed history would be too long to give here, have not had attacks for six, eight, and even twelve years, when beforehand they had one or more attacks every year, either articular or visceral, for these manifestations of the disease are particularly benefited by Contrexeville.

"The waters of Contrexeville are often very useful in chronic gout. We have used them several times in cases of gout of long standing and we have found the results very beneficial."

Dr. Potton, himself a sufferer from gout, and fighting, as he says, "pro domo sua," has published[1] a series of papers comparing the use of some of the mineral waters in gout; and speaking of visceral gout, he says that in these cases he chooses the calcareous magnesian waters of Contrexeville, as being preferable to all other remedies. "I do not know," adds the author, "a surer means for regulating the functions in this kind of gout."

Vesical Catarrh, though sometimes met with in young men, is essentially a disease of old men, in whom the voluminous prostate and the uncontractable bladder occasion the stagnation of the urine, and its decomposition before its emission.

There is, perhaps, no disease against which so many medicines have been directed as against vesical catarrh.

At Contrexeville, after patients have drunk the water for a few days, the urine, which had been cloudy, thick, ropy, became clear, its mucous deposit diminishes, it emits a less disagreeable odor, the inclination to make water, which had formerly wakened the patient seven or eight times during the night, disturbs his sleep but once or twice; the feeling of heaviness in the abdomen passes off; micturition becomes easier, and the patients are delighted to see with what force they expel their urine. This improvement goes on increasing day by day, and ends in a definite cure after a season or two.

"The effects of the mineral waters of Contrexeville," says Dr. Civiale, "consist especially in restoring the vesical contractility, which is always weakened in this disease. Many of my patients, affected at the same time with atony and catarrh, whom I advised to try the waters of Contrexeville, obtained such good results from them that they returned there of their own accord."

Hepatic Colic.—The waters of Contrexeville have given equally remarkable results in cases of hepatic colic, particularly in debilitated patients. The laxative effect produced by the ingestion of the waters renders the indication precise in the case of hepatic patients whose intestinal functions are hindered. The Contrexeville waters possessing tonic qualities, are of great utility in the case of patients who have been debilitated by numerous crises.

Diabetes.—Our personal experience confirms in all points the results which were described by Dr. Bronguiart, in 1876, in a lecture on the treatment of gouty diabetes, at Contrexeville. A number of gouty patients are attacked with diabetes and many of them are aware of it only when the disease has become serious enough to render the cure problematical.

Among the cases we have observed we will mention two patients whose urine contained respectively one hundred and one hundred and twenty grammes of glucose to the litre. We saw this rapidly disappear under the influence of the treatment and without any special alimentary *régime*. In one of the cases the sugar reappeared the following year, the other we never saw again. But many other examples of gouty diabetes, with moderate quantities of sugar, have been followed by us, and the treatment always very happily modified the constitution.

When patients who had escaped our observation in the intervals of treatment came back to Contrexeville, the glucose, if it still persisted, was always to be found in much smaller quantities than the preceding year.

Among other affections which are benefited by the waters of Contrexeville we must mention dyspepsia, diseases of the prostate, chronic urethritis, spermatorrhœa, and uterine catarrh.

The Third Mexican Medical Congress will be held in Guadalajara in 1896, under the presidency of Dr. Rafael Lavista.

Clinical Department.

A CASE OF CROUP TREATED BY ANTITOXIN.

By FORBES R. McCREERY, M.D.,

NEW YORK.

The question of the value of antitoxin is one of such great importance that I feel it desirable that even such individual cases as the following should be reported. It, of course, as will be seen, proves nothing for or against the remedy. Nevertheless, it is of interest, the more so as nearly all the reports heretofore published have been of hospital cases.

The patient, a child aged twenty-two months, was taken ill on the morning of December 2d. The symptoms first noticed were hoarseness, cough, and slight difficulty in breathing. These symptoms became gradually more marked. They were worse at night, but persisted throughout the day of the 3d. I first saw the child December 4th, about 10.30 A. M. There was no membrane visible in the throat, but the signs of laryngeal stenosis were well marked, though not extreme. The character of the voice and cough, the marked stenosis, and the history of the case, all pointed to the diagnosis of a membranous and presumably diphtheritic croup. That evening the stenosis was more marked, and I feared that intubation would be necessary before morning. I concluded, however, to try first the effect of antitoxin, and accordingly procured some from the Pasteur Institute and injected 13 c.c. The rectal temperature at the time was 101° F. The following morning I found the child free from laryngeal stenosis, but with a temperature of 102° F. I learned that the dyspnœa had begun to diminish within two hours after the injection. I injected about 6 c.c. more of the serum. That evening the child was still free from symptoms of stenosis and the temperature had risen to 105° F. I was informed that the child had been apparently delirious during the afternoon. The bronchi were full of coarse râles, and I thought I detected a patch of pneumonia. The child was given a tepid bath and an aconite mixture ordered. The next morning the temperature had fallen to 102° F. No pneumonia could be made out, and there was no stenosis. That day I received a report from the Board of Health stating that no diphtheria bacilli had been found in culture made from the pharynx; two subsequent examinations failed to reveal any. The child convalesced rapidly, without further symptoms than those of a moderate bronchitis. I may add that she had suffered from a severe bronchitis last spring.

Apart from the injection, the child was treated from the morning of the 4th by calomel fumigations and strychnia and iron internally.

I think this case is an example of a class often met with. I mean a class of cases in which all the symptoms indicate a membranous, and, therefore, probably a diphtheritic, laryngitis, but in which no membrane is visible, and in which no diphtheria bacilli are found in cultures. These cases, in my experience, are always serious, often require intubation, and are often fatal. It is safer always to assume that they are diphtheritic and to treat them accordingly.

In conclusion, I would repeat that the case proves nothing for or against the remedy. Nevertheless, the rapid disappearance of the stenosis seemed to have been due, in part at least, to the injection of antitoxin. In like manner, the sudden rise of temperature, and the delirium, may have been caused thereby.

129 East Fortieth Street.

Dr. Paris died recently at the age of ninety-three. He was formerly physician in ordinary to Louis Philippe.

POISONING BY POTASSIUM CHLORATE.

By THEODORE POTTER, M.D.,

INDIANAPOLIS, IND.

At the meeting of the Marion County Medical Society, October 2, 1894, four cases of potassium-chlorate poisoning were reported by Drs. J. T. McShane, S. P. Sherer, Florence Hays, and myself. Two of these were fatal. The reports in brief may be found in the minutes of the meeting as published in the Indiana *Medical Journal* for November. The case which came under the writer's observation was as follows:

On June 21, 1894, I was called to see Mr. T——, aged forty-seven, who was said to be suffering from painful bowel disturbances. He had been taken ill twelve hours before. He had vomited once or twice, and at the time of my visit complained chiefly of pain over the epigastric region and over the lower abdomen, with diarrhœa, which was assuming a dysenteric character. There was some rectal tenesmus, with the passage of small quantities of mucus and blood with the stools. Temperature 102° F., pulse 108 and weak. The bowels were ordered washed out, and bismuth and small doses of chlorodyne given.

On June 22d the morning temperature was 104.4° F.; evening temperature, 104° F., having been modified by small doses of acetanilid. On the 23d the temperature was 103° F. The fact that the patient did not pass much urine, and that there was some dysuria, was supposed to be sufficiently explained by the cholera-morbus-like attack of bowel trouble.

On the 23d, in spite of amelioration of the bowel disturbance, the other symptoms were no better, but in some respects worse. The patient complained at times of being cold; his feet were cold; fingers, nose, and cheeks cyanotic; he repeatedly broke into profuse sweat. The urine was scanty and there was considerable dysuria; rectal tenesmus moderate, with passage of some mucus and blood. The abdomen was very tender below the umbilicus and in the epigastric region. Weakness and prostration were out of proportion to the bowel disorder.

My attention was now called to the fact that the urine and the fæces were both black. The latter, it was thought, might be due to the bismuth taken, though the color was of an inky character, which, together with the black urine, aroused my suspicion. Inquiry was at once made in regard to the use of carbolic acid or potassium chlorate.

The patient stated that on the 18th, having a slight sore throat, he had bought two cents' worth of the latter drug, getting about two teaspoonfuls. This quantity he had eaten on the 18th and 19th. The poisonous effects showed themselves during the night of the 20th. The diagnosis of potassium-chlorate poisoning was now made.

The bowels were flushed repeatedly with hot water; large hot poultices placed over abdomen and back. He was ordered hot sitz-bath, castor-oil was given, and he was directed to drink large quantities of weak flax-seed tea. Small doses of Dover's powder were also given.

On the 25th the morning temperature was 101.5° F. There was dribbling of urine, and examination showed retention; urine still very dark, though not black. In the evening the catheter drew about twenty ounces of better-looking urine. The stool resulting from the castor-oil was more natural in appearance, but subsequently and for a week the fæces were almost black, though the bismuth had been discontinued.

The treatment was continued as above, except the poultice to the back. The diet was milk, soup, broth, and fresh beef-juice. At times watermelon-seed tea was substituted for that made from flax-seed. The catheter was used twice daily till July 2d, the character of the urine in the meantime improving.

The patient had for several years shown some signs

of slight prostatic hypertrophy, the suspicion being now confirmed by rectal examination. The long-continued dysuria and necessity for the catheter were, I think, in large measure due to the increase of this former trouble. From June 30th to July 9th the bladder was daily washed, at first with boracic solution, later with bichloride of mercury, 1 to 16,000. On July 9th the pain in the renal regions, both sides, increased and became severe. Up to this time it had been slight. Under the vigorous application of hot baths and large hot poultices this subsided. On the evening of the 9th Holland gin was given, a teaspoonful every two hours. Within twelve hours improvement in the urinary symptoms was marked, due doubtless to the juniper in the gin. The use of the catheter was stopped on the 10th. On this date the temperature and pulse became normal.

In the meantime the bowels had, with periods of remission, gradually improved. By July 10th the abdominal tenderness had largely passed away, and with it the gaseous distention, which had been present almost from the start. The movements had lost the black color, their appearance indicating simply a catarrhal condition of the bowels. It is of interest to note, as showing the violent disturbance of the intestines, that for two weeks after the beginning of the attack all solid food, which was several times tried, passed through with hardly any appearance of digestion. The urine was examined during the height of the attack for albumin and sugar. Neither was found; casts were not looked for. It is to be noted that this examination was not made till after the treatment had induced a marked increase in the amount of urine passed. I regret that the blood was not examined.

After the cyanosis passed away the appearance of the patient was that of marked anæmia, which was still pronounced at the time of my last visit, on July 14th. He was ordered to continue iron, which he had been taking for a week, and a short time after was sent to West Baden Springs, this State, to recuperate.

During his illness the patient was seen by Dr. H. M. Lash, and by Dr. Thompson, of Irvington.

In looking back over the case the things which stand out most prominently in the clinical history are, the violent irritation of the bowels, the equally violent urinary disturbance, the great prostration, and the evidences of profound alteration of the blood.

DEATH BY DROWNING.

By N. L. NORTH, M.D.,

BROOKLYN, N. Y.

In a recent case of supposed drowning doubts were cast upon the cause of death because little or no water was found in the lungs, naturally exciting the inquiry, What is the mode of death by drowning? The answer, "By asphyxia," is not enough, as asphyxia is the result of the absence of air, the respiratory medium in the lungs, and may result from numerous causes, as from enfeebled respiratory power, torpor of the medulla oblongata, enfeebled action of the heart, or from various mechanical causes, or from inhalation of gases. So it would seem that water in the lungs is no necessary part of the process of drowning. It is a fact, also, that in many cases of drowning no water is found in the lungs, nor even in the bronchial tubes. Taylor cites case after case of undoubted deaths by drowning in which no water was found in the lungs, but instead only a frothy mucus about the lips and nostrils. Water may be found in the stomach, having been swallowed during the struggle; but if the individual be stunned before falling into the water, or if in any way death had been caused previously, water would not be found in the stomach. If the person were supposed to have been drowned in the ocean, bay, or Sound, and no ocean (salt) water were found in the stomach, doubt would then be cast upon the mode of death, as a strong probability would exist that death antedated the submersion.

Again, a purely accidental drowning would be more likely to show water in the lungs, the bronchial tubes, and trachea than suicidal or intentional drowning, as one going into the water intentionally would almost involuntarily take a deep inhalation before the plunge, and the lungs, being filled with air, that would prevent the water entering; while, when accidentally falling into water, the inhaling movement would naturally follow the shock of the immersion, and water, instead of air, would be drawn in by the inspiration.

Drowning, then, asphyxia by submersion, "is not owing to a certain quantity of liquid being introduced into the alimentary or air-passages, but simply to the interception of air, and of the respiratory phenomena;" hence the post-mortem appearances other than those which show externally—the cold, pallid, corrugated skin, with the half-open eyes, swollen tongue, partly protruded, and with the lips and nostrils covered with frothy mucus—would be those of suffocation and consequent upon the sudden and complete suspension of respiration, the right side of the heart and the lungs gorged with blood, the bronchial tubes and trachea more or less filled with frothy mucus, and not necessarily anything else. There may be water in the lungs and the bronchiæ and the stomach, or there may not, the condition may be the same, and only the same as if the person had been confined in nitrogen gas, or as if the individual had been simply smothered, suffocated, and died from lack of oxygen, or as if he had been in a vacuum, except that there would be the added symptoms caused by the removed air-pressure.

A CASE OF OPIUM-POISONING TREATED BY PERMANGANATE OF POTASSIUM.

By R. G. EBERT, M.D.,

ASSISTANT SURGEON UNITED STATES ARMY.

Mrs. F——, mulatto, aged twenty-three, took an unknown quantity of morphine solution at about 10.30 A.M. An hour and a half later she was found by her neighbors in an unconscious condition, and medical attendance was summoned. At 12.40 P.M she could not be roused; gave no response to external stimulation; inability to swallow; extremities, cold; cornea, insensitive to touch; pupils, contracted; pulse, weak but regular, and about seventy; respirations, superficial, and not to exceed eight per minute. At this time no history of taking or time of taking the opiate was obtainable. She was too deeply narcotized to attempt evacuation of the stomach by apomorphine. Treatment was one-fiftieth of a grain of sulphate of atropia and two drachms of whiskey hypodermically.

Respiration and pulse, the former slightly, the latter markedly, responded to this medication. While awaiting arrival of stomach-pump, heat and counter-irritants were applied to the extremities.

At 1.5 P.M. an additional one-fiftieth grain of atropia was given; at this time the post surgeon, Major Wilcox, arrived, and at his suggestion permanganate of potash, which was being prepared for irrigation of stomach, was injected deeply into the tissues of both thighs in a concentrated solution, quantity not measured, but assumed to be between one and a half and two grains of the salt. In less than three minutes (only time sufficient to lay aside the hypodermic syringe and render the stomach-tube flexible) she responded to the stimulus produced by the passage of the œsophageal tube through the pharynx, the first reflex obtained. A pint and a half of a strong solution of permanganate was thrown into the stomach, further introduction being arrested by regurgitation of the fluid, and on withdrawal of the

tube copious emesis followed; the returning liquid was not wholly discolored.

Further active medication ceased. Coffee and nursing meeting all requirements. At 1.45 P.M. consciousness was manifested; fifty minutes later questions were answered intelligently, and the facts elicited that morphine had been taken at the time above mentioned.

The first injection of atropia had no perceptible influence on the pupils; the second was so shortly followed by the permanganate that no time had been allowed to show its effects, if there were any, upon the eye. An hour afterward the size of the pupil was still below normal. The good results, so rapidly and markedly obtained, are attributed by Dr. Wilcox and myself entirely to the permanganate.

FORT HUACHUCA, ARIZONA TERRITORY.

THE EMPLOYMENT OF PILOCARPINE IN THE TREATMENT OF URTICARIA.

BY AUGUSTUS A. ESHNER, M.D.,

ADJUNCT PROFESSOR OF CLINICAL MEDICINE IN THE PHILADELPHIA POLYCLINIC.

I AM prompted to make this report by the recommendation of Abrahams,[1] of pilocarpine hydrochlorate in the treatment of acute and chronic urticaria, with a recital of three illustrative cases, and by the confirmatory report of McBrayer.[2]

A married woman, forty-three years of age, came to my service at the Polyclinic several weeks ago, with a history of having suffered for two months, intermittently, with an urticarial eruption upon the elbows, forearms, and legs, recurring for periods of two or three weeks at a time, at intervals of about a week. There was no history of the ingestion of shell-fish or other article of diet to which etiologic significance could be attached. The woman was constipated and complained of attacks of smothering attributable to distention of the stomach. No heart-lesion could be detected, and the urine presented no abnormality. Other symptoms of vasomotor ataxia were wanting. On inquiry it was learned that a dog was kept in the family, but investigation disclosed a freedom from fleas, and no other member of the household suffered as did the patient. Pills of pilocarpine hydrochlorate, gr. ½, three times daily, were prescribed, and the woman returned in a week much improved. Thereafter no more "hives" appeared, and four days later the woman reported that she had not felt so well for two years.

My employment of pilocarpine in this case was purely empirical. The drug has such a pronounced effect upon the circulatory and secretory activity of the skin, and I had observed such strikingly favorable results from its systematic employment in the treatment of erysipelas, that I was led to its use for the relief of urticaria. I fancy, too, that the drug is worthy more extended application in the domain of dermato-therapy than it has heretofore received. I should prefer its subcutaneous injection when the patient is under immediate observation, but I feel safer in directing its administration by the mouth in the case of out-patients.

FRACTURE OF THE FOURTH CERVICAL VERTEBRA AND RECOVERY.

BY CHARLES J. RINGNELL, M.D.,

MINNEAPOLIS, MINN.

ON August 3, 1893, Julius A——, a farmer, aged nineteen, came under my care at the Deaconess Institute, presenting all the symptoms of a "broken neck." After having made a careful examination, I arrived at the conclusion that the laminæ of the fourth cervical vertebra were fractured. Crepitation could be elicited. Two days previous he was about to take a bath in a small river, eighty miles from this city. He jumped in the river head first, thinking the water was deep; but to his misfortune struck the bottom and became unconscious immediately, in which state he remained for about five minutes. His companions noticed the condition he was in and carried him to the shore. After regaining consciousness he was unable to move any part of the body, excepting the head. Pain was felt only in the neck. The next day he was sent to the hospital, and when first seen he presented the symptoms above stated, with these additions: Temperature, 103° F.; pulse, 72; labored breathing; retention of urine and fæces; anæsthesia of lower extremities, extending over the abdomen, and complete paralysis of lower extremities, bladder, and lower bowel. The arms could be raised slightly, but fingers could not be moved. Complained of thirst, was unable to take any nourishment, and could not sleep. Bowels and bladder were attended to, and head fixed.

The following three weeks he was expected to die every day, as no improvement could be noticed. Temperature ranged from 102° to 105° F. Pulse never went over 72, but was generally about 65. Vesication and head-sores developed. After the third week the temperature commenced to sink, and a slight improvement could be noticed daily.

In the meantime quite a severe cystitis had developed, although every precaution had been taken in regard to cleanliness. This, however, abated, and was followed by incontinence, and it became necessary to keep a urinal in the bed to receive the urine, which came drop by drop until the twelfth week, when it could be retained for an hour's time. In the eighth week anæsthesia commenced to disappear on the right side, and in a short time on the left also. The paralysis gradually disappeared in the same order.

Improvement continued, and about December 1, 1893, he was able to sit up in the bed, having his head supported. About January 1st, this year, he commenced to walk with the aid of a chair. He remained at the hospital for ten months, and his improvement was uninterrupted. The enlargement in the neck was quite marked when discharged. Head being fixed with appropriate dressings, the other symptoms were treated as they appeared. Iodide of potassium in increased doses was given from the sixth week, and later on electricity and massage.

A few days ago I had a letter from my patient, in which he stated that he has recovered almost entirely, and that he has been attending school ever since last fall.

This case has been quite interesting to me, and might prove so to some fellow-practitioner.

LOOSE BODY IN THE KNEE-JOINT.

BY HUGO E. WAUGELIN, M.D.,

ST. CLAIR COUNTY PHYSICIAN, BELLEVILLE, ILL.

MR. A. M——, a farmer, was admitted to the St. Clair County Farm in June, 1894. He was admitted as a patient with inflammatory rheumatism. He gave a history of two years' suffering, all his trouble being located in the left knee-joint. Examination of the knee showed it to be very much swollen and exceedingly painful to touch, and almost immovable. Local applications and rest in bed with the leg elevated reduced the symptoms very materially.

About a week after, at another examination, I found what later proved to be the cause of the trouble. There was a loose body floating in the joint. This body was movable to almost all parts of the knee, both anterior and posterior, and could be carried about six inches above the patella. At times it would be lost, and then could not be found after the most diligent

[1] MEDICAL RECORD, September 15, 1894, p. 342.
[2] Ibid., November 3, 1894, p. 564.

search. I have hunted as long as an hour for it and been unable to locate it. Twice I was ready to remove it and it slipped from my fingers and was lost. Finally I located it about three inches above the patella to the inner side of the thigh. I then passed a needle under it and fixed it so I could cut down on it. The incision was about two inches long. With a pair of thin forceps I removed the body, stitched up the sac with catgut, closed the external wound with the interrupted stitch, and put on a dry dressing. The patient made a good recovery.

This body which I removed was globular in form and about half an inch in size, covered all over with little knobs which made it look very much like a blackberry, only that it was perfectly white. Microscopical examination showed it to be of bone tissue.

How did this piece of bone get into the joint? The only explanation I know of, and I think probably it is the correct one, is this. About two and a half years ago he had his knee caught between the wheels of a wagon, which laid him up for some time, and after that thought he had rheumatism in his knee. To my way of thinking, it is more than likely that a piece of bone was knocked loose and floated in the joint, causing his trouble.

Five months after I saw him, and he was doing all the work on a farm, and had as good use of his left knee as his right.

A UNIQUE CASE OF COMBINED ANTRUM AND MASTOID DISEASE.

By CHARLES H. BAKER, M.D.,

BAY CITY, MICH.

The following case is, I believe, unique from the occurrence simultaneously of abscess of the antrum of Highmore and of the mastoid antrum, and because the latter was the direct result of the former.

Mrs. Mary N——, fifty-eight years of age, had in April, 1893, what she calls hay-fever and sunstroke (?), which was accompanied by swelling between the eyebrows and in front of the left ear; considerable pain in the cheek and a profuse nasal discharge, which lasted two or three weeks. She was treated by the use of the nasal douche, prescribed by a physician, and remained well until September 27, 1894.

At this time she nursed a very severe case of puerperal fever, losing much sleep and becoming much exhausted. While overheated, and in this condition, she laid down for a nap between two open windows, and was awakened by severe pain in the left cheek.

This was soon followed by a thick, foul, and bad-smelling discharge from the left nostril, and to relieve it she again resorted to warm douches, which she continued a week, when one day she took cold water and snuffed it into the nostril from the palm of the hand.

She was immediately seized with pain in the middle ear on the left side, which increased until the exudation forced an opening through the tympanic membrane; no relief followed the perforation, and the tissues behind the ear rapidly swelled. On visiting her with the attending physician, it was decided to drill into the mastoid and also the antrum, which was done, finding a little pus in the mastoid antrum and a great deal of foul pus in the antrum of Highmore. The opening into the latter was made through the socket of the first molar, which was extracted for the purpose.

A soft rubber drainage-tube was used, for want of a regular antrum-tube, and the teeth adjoining the opening being absent, it was stitched to the gum in order that it should not be lost in the antrum or swallowed during sleep.

The patient was a confirmed morphine eater and in the habit of consuming large quantities of the drug. During her recovery she had a mild attack of facial erysipelas, which, with the use of carbolic acid and compound tincture of iodine, equal parts, applied to and around the infected area, was easily controlled.

The mastoid opening was completely healed in two or three days, the discharge ceasing promptly. The antrum was irrigated with dilute hydrogen dioxide, followed after a few weeks by potassium permanganate solution, and at the present writing, three months after the operation, she is still cleansing the cavity by irrigation from below, causing the fluid to issue from the nose. The secretion of pus is very small in amount, and will no doubt in a short time more entirely cease.

In a series of sixteen mastoid cases, this is the second in which water in quantity, douched or snuffed into the nose, has carried infection into the middle ear, and the necessity of care in cleansing the nose cannot be too strongly insisted upon. Cold water, by its action on the erectile tissues of the nose and pharynx, is more liable to cause swelling and retention long enough for mischief to be done, but any fluid which enters the Eustachian tube after first passing over a suppurating nasal membrane is dangerous.

In this connection I have often noticed an anatomical peculiarity which predisposes to the entrance of secretions into the Eustachian orifice, and so far as I have examined it has been present in all my cases. The top of the Eustachian tube, in a normal throat, protrudes from the side of the pharyngeal vault somewhat as a dormer window does from a roof, thus shedding the mucus to either side and causing it to flow down the pharynx.

But in these and some other cases, I have seen the opening nearly or quite flush with the side wall of the pharynx; or even having the lower edge of the opening the most prominent, thus predisposing to the entrance of fluids into the Eustachian tube.

PERMANGANATE OF POTASSIUM IN MORPHINE POISONING.

By WILLIAM E. PUTNAM, M.D.,

WHITING, IND.

Had I known the value of permanganate of potassium sooner, I might have saved the lives of two men who have died from morphine poisoning in less than two years. But thanks to the discovery of Dr. Moor, my third case was saved.

Mrs. ——, aged forty-five, took at least two ounces of laudanum. When I was called the pupils looked the size of a pin's point, the hands and feet were cold, and the nails blue. Respiration was irregular. I sent first for my bottle of one-grain tablets of permanganate of potassium. Second, for my colleague, Dr. J. R. Harvey. Our diagnosis was death in thirty minutes unless permanganate of potassium would save the woman's life.

Dr. Harvey, like Dr. C. Monroe McGuire, had no faith in permanganate of potassium, simply because he had never fitted the drug to the right case.

We dissolved fifteen one-grain tablets in four ounces of water and two ounces of white wine vinegar, but we could not get the patient to swallow. I picked up a piece of rubber hose and cut off four inches, and with this over a piece of pine stick I made a gag and inserted it between the jaws. I then held the nose tightly and Dr. Harvey fed the woman the permanganate of potassium solution with a tablespoon. We gave forty-five grains or more, and slowly our patient began to recover. She was very low for about four days, her mouth and throat, and I suppose stomach, were thoroughly blackened and dry and sore from the permanganate of potassium.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, March 9, 1895.

THE SIN OF SUBSTITUTION.

WE have recently published under the above title several of the numerous communications received in reference to the dishonesty of certain druggists. Now, while we do not believe for one moment that the dispenser is an untrustworthy man by nature, there seems to be something in the nature of his business, as conducted in different places, that gradually perverts his moral sense of rectitude and slowly leads to the crime of which so much complaint has of late been made.

To one who has given much thought to the matter, and followed the burden of these complaints, it is clear that the druggist does not begin dishonest, but that unless he exercises the greatest and most constant care he gradually is led into an easy way of looking at the physician's rights, until by a graduated course of counter-prescribing, playing the doctor, recommending something of his own as better than that prescribed, his sense of right becomes so blunted that it is no longer difficult for him to replace an expensive drug or one not in stock with a substitute.

While it may be possible that some of the talk has been instigated by unfriendly competitors, still there is unquestionably cause for much righteous indignation and bitter complaint.

The suggestion of our California correspondent, published a fortnight since, is a good one from a theoretical side, and might practically settle the question for a limited community in which the evils were pronounced. It is, however, not expedient for physicians to go generally into the drug business. There are serious objections to it, and the two professions must of necessity remain separated. The evils complained of must be remedied, and in time, no doubt, will be. In self-defence the druggist must reform. The pressure brought to bear upon him to cause this reformation will come first from us as physicians, but must be more directly applied through the schools and boards of pharmacy. They should take the initiative, and devise some stringent way of dealing with those who in disgracing themselves bring discredit upon their calling. If examples were made of some of the wrongdoers by legal proceedings much substantial good would be accomplished. It would, of course, entail some trouble in obtaining evidence, but the desirable end would more than justify the means. Perhaps if more care were taken by physicians to ascertain the facts of substitution the evil might be found to be still more prevalent than has been stated.

THE TREATMENT OF INSANITY BY INOCULATION.

SOME years ago Dr. Colin M. Campbell writing on the effect of typhoid fever said: "Perhaps at some future time when the specific fevers have become more manageable, acute attacks of insanity may be cured by inoculation." In connection with this he cited some cases showing that typhoid fever sometimes cuts short an attack of insanity.

Guesinger states that the course of the psychoses is sometimes favorably influenced by intercurrent fevers, such as pneumonia, typhoid, variola, etc. Willerding, in an article on this subject, reports a case of mania cured by an attack of pleurisy (Allg. Ztschr. f. Psych., 1888, Bd. 20, h. 1). Schutze reports a case of cure following diphtheria, and Dinter one following facial erysipelas.

On the other hand, Dr. Granger, who has studied the effects of intercurrent diseases upon two thousand cases of insanity, concludes that upon the whole such diseases have little effect. He seems to think that painful affections are more beneficial than febrile. Out of 77 cases of insanity attacked by dysentery 4 only were mentally improved, and these only temporarily. Granger attributes much more therapeutic potency to injuries than to disease. He cites six cases in which jumping from heights caused shock and injury, and in all these marked improvement followed.

We recite the foregoing evidence in connection with certain reports telegraphed from Vienna to the effect that Professor Wagner is successfully treating the insane with injections of tuberculin. It will be seen that the experience of alienists does not show that much good comes from the induction of fever in the insane, and it is most unlikely that any permanent good can come from such treatment.

THE DANGER OF TRANSFERRING THE CARE OF NEW YORK CITY'S INSANE TO THE STATE.

As will be seen elsewhere, a bill has been introduced into the State Legislature providing for the transferring of all the insane of New York to the care of the State. This bill is said to emanate from the State Charities' Aid Association and it presumably is carefully and wisely drawn.

But we foresee many dangers ahead in this plan and it behooves those interested in our charities to go very slowly.

The transfer of the county insane to the State was a measure theoretically wise and was very generally approved. But man proposes and politics disposes. Our State institutions are threatened with an invasion by the machine. Already two of these institutions have succumbed and become creatures of politicians. The simple transfer of our city institutions from one party to the other would do no good to the insane, or to sci-

ence, or to the community at large. It would result in filling the medical positions, so far as possible, with up-country political doctors, and the subordinate positions with out-of-town political heelers. If we must have politicians in these places it is better, at least, to have those who are known to the community and who are in sympathy with its interests.

It would be quite possible to reform our present asylums while under the city's control. A State machine is no better, and is rather less intelligent, than one of city origin.

OUR MATERIA MEDICA.

The discussion upon the subject of materia medica and therapeutics held before the Academy recently, was one of great practical interest, and it will, we trust, be productive of good to the profession at large as well as the student.

The conclusion which one reaches from reading the remarks of the speakers is, that we have too many drugs, too many preparations of drugs, and too much teaching of materia medica. This leads to evils in many directions. The druggist is obliged to encumber himself with much useless and expensive material; the student has to load his already overburdened memory with a mass of useless botanical or pharmaceutical facts, and the practitioner is so embarrassed with his richness of material that he speedily forgets a large part of his materia medica, and settles down to certain routine remedies which chance successes rather than ripe experience and good judgment select.

We hear, almost with amazement, of the countless preparations of iron, mercury, and cathartics which are officinal, and the names of which are drilled into the students during the "cram quizz." The endless list of antipyretics, analgesics, hypnotics, and antiseptics which modern chemistry supplies, makes the task of learning materia medica still greater.

The remedy is largely in the hands of the teachers, and those who provide our Pharmacopœia. One of the easiest and simplest measures is that of dropping many of the unnecessary preparations of drugs. Mercury or iron can easily be given in half a dozen forms, and many of the officinal cathartics are simply of legendary value.

The dropping of special drugs from the list is a matter of more difficulty, yet something can be done in this direction. An analysis of prescriptions shows that the number of drugs in actual use is not very great, and by a large and comprehensive examination of the drugs in actual use, many superfluities can be eliminated.

LEGISLATING FOR THE KEELEY CURE.

The Massachusetts Legislature has before it a bill compelling the use of the so-called Keeley cure in the Massachusetts Hospital for Dipsomaniacs.

If this law were amended so as to compel the careful testing of this and similar "cures," we doubt if opposition would be met, despite the repugnance of physicians to dealing with secret remedies of possibly dangerous character. But to enforce the use of such a method would be unjust and unwise. We have no doubt that the physicians of the hospital in question do apply all that is valuable in the half-dozen inebriate cures that have sprung up in the last few years. Strychnia, atropia, apomorphine, simple bitters, combined with all possible measures to stimulate the will, arouse self-respect, and improve the general health of the patient, will do much for inebriates; no special "cure" can do any more.

News of the Week.

European Bacteriologists very Busy.—The following note from a Berlin correspondent appears in *The Sun*: "This is no time for young bacteriologists to come to Europe for instruction. The men foremost in that field of science are too busy with their investigations to give lectures. A young bacteriologist who has been hanging around the University of Berlin for a couple of months, catching up any scraps of information that his professors might be good enough to let drop, and looking through microscopes in the hope of discovering something that he didn't know before, went off to Paris to see if he could find some one there who would stop his investigations long enough to give him instruction. He found even a worse state of affairs there. The scientific men of to-day who are making investigations in bacteriology are as feverish as were the prospectors for gold in California half a century ago."

Manhattan State Hospital.—Assemblyman Conkling has introduced a bill for the transfer of the dependent insane of New York County to the care of the State. This measure, which, it is understood, emanates from the State Charities Aid Association, provides that the New York City asylums for the insane, located on Ward's Island, New York City, and at Central Islip, Suffolk County, shall be transferred to the care and custody of the Manhattan State Hospital, to be established by the act. Among the provisions of the bill are the following: The whole of Ward's Island, with its buildings and the equipment of the existing asylums, are to be leased to the State at a rental which is to be the equivalent of interest at the rate of three per cent. upon the sum of $2,500,000. It will be remembered that in 1892 the State sold to the city of New York one-half of Ward's Island for the sum of $1,000,000. It is therefore assumed that the entire island is worth at least $2,000,000, and the value of the buildings which have been erected upon the island for the purpose of asylums for the insane is estimated at $500,000.

The Central Islip property is also to be leased to the State at a rental which shall be the equivalent of the interest at three per cent. upon $400,000, which is less than the actual amount which has been expended for buildings on the property. It is provided that either of the leases may at any time be surrendered by the State, or may be terminated by the city by five years' written notice to the Comptroller of the State. In case either of the leases shall be terminated by the city of New York, the State is to be reimbursed for buildings which it may have erected and improvements which it may have made, the amount to be determined

by appraisement by a commission of five citizens, two of whom are to be appointed by the Governor, two by the Mayor of New York City, and a fifth by these four. The Manhattan State Hospital is to be governed by a board of seven managers, appointed by the Governor and confirmed by the Senate, and their powers and duties shall be the same as those of the managers of the other State hospitals. Subject to the civil service laws of the State, the managers are to appoint the general superintendent, who in turn appoints all subordinate officers. The Commissioners of Charities and Correction of New York City are to surrender the lands and buildings of the existing asylum, with their furniture, fixtures, stock, and supplies then on hand, to the newly created State Hospital on October 1, 1895. An appropriation of $25,000 is made for the lease or purchase of a dock and for the purchase of a steam ferryboat. The present officers of the asylums are continued in office during the pleasure of the managers, subject to the civil service rules applicable to the other State hospitals. On and after October 1, 1895, the Manhattan State Hospital will come under the provisions of the State Care Maintenance Act, and will be organized and maintained as are the other State hospitals for the insane.

Convicted for Grave-robbing.—Three men who robbed a grave near Franklin, Ind., have been convicted and sentenced to six years' imprisonment. The body was found in the dissecting-room of the Indiana Medical College.

Treatment of Influenza in London.—Influenza continues to be extremely prevalent in London. A member of Parliament who is just recovering from his fifth serious attack, has written to the papers advising the sufferers to mix fifteen grains of citrate of potash in a tumbler of hot water with the juice of one lemon, and to sip this mixture day and night. The idea that fifteen grains of citrate of potash will do any good in influenza, will surprise medical men at least.

Exit Pithecanthropus Erectus.—Dr. Harrison Allen (*Science*) says that the molar tooth of Dr. Dubois's "Missing Link" is human and not at all simian; the skull is also human and so is the femur. The bones found, in fact, are all human and not simian. This view is also taken by Lydekker in *Nature*.

Medical Society of the Missouri Valley.—The Medical Society of the Missouri Valley will meet at Sioux City, Ia., March 21st.

A Doctor Shot.—Dr. A. S. Bickel, of Florid, Ill., recently called on a farmer's wife who was seriously ill. While the doctor was warming himself by the fire, the husband came to him and ordered him out of the house, saying his services were not needed, at the same time brandishing a shotgun. As the doctor was making a hasty exit, the farmer shot at him, the entire charge entering his right side. Medical aid was summoned, but it is supposed the shot is fatal. The patient had ordered the doctor, contrary to her husband's wishes, and this enraged him. Wives will consult their husbands in Illinois hereafter before sending for a doctor.

Kings County Medical Association.—The following officers have been elected for the year 1895: *President*, Dr. J. C. Bierwirth; *Vice-President*, Dr. N. W. Leighton; *Recording Secretary*, Dr. F. C. Raynor; *Corresponding Secretary*, Dr. H. C. Riggs; *Treasurer*, Dr. E. H. Squibb.

The Mississippi State Medical Association meets in Jackson on Wednesday, April 10th.

Appointments at Jefferson Medical College.—Dr. William Thomson, who has been Honorary Professor of Ophthalmology, has been given the full professorship. Dr. Howard Forde Hansell, who has been Chief Clinical Assistant, has been made Clinical Professor of Ophthalmology.

The Regulation of Doctors' Fees.—A member of the Illinois State Senate, whom we may term O'Dwyer, has introduced a bill into the Senate regulating the fees of physicians and surgeons. The *Journal* has not been favored with a copy of this bill, but we learn by the daily press that the bill proposes to fix the maximum fee for any surgical operation at $100. Senator O'Dwyer is given credit by the veracious chronicler of the press for being the first to bring this subject to the attention of the law.—*Journal of American Medical Association.*

The Death of M. Alphonse Guerin, of Paris, is announced as having taken place on Thursday, February 21st. He was seventy-eight years of age.

A Statue of Dr. Gross.—The House passed the Senate bill granting permission to the American Surgical Association and the Alumni Association of the Jefferson Medical College to erect a statue to the memory of Samuel D. Gross in this city. The bill appropriates $1,500 for a pedestal.

The Congress of German Surgeons.—The Twenty-fourth Congress of German Surgeons will be held at Berlin from April 17th to 20th. Professor Gussenbauer will preside.

A Monument to Billroth.—A monument to the memory of Professor Billroth will soon be erected in the court of honor of the University of Vienna. The Council of the Faculty has also decided to erect a monument to Skoda and Rokitansky.

How should the Surgeon Clean his Hands?—In Germany the usual method for surgeons to clean their hands is that of Fürbinger. It consists in brushing the hands and nails with soap and hot water, then dipping them in an eighty per cent. alcohol solution, and finally washing with a two per cent. sublimate of mercury, each part of this proceeding to last one minute. Recently Reinecke, of Leipzig, has asserted that a sure disinfection of the hands may be obtained by rubbing them with alcohol only and washing afterward with pure sterilized water. The alcohol owes its power to its action in dissolving the sebaceous substance on the surface of the skin, and enabling the bacteria which adhere to it to be easily washed away. Instead of brushes, which are difficult to clean and which irritate the hands, he recommends loofah sponges. Another reformer in this matter is Dr. Schleich, who rejects all brushing, and only washes the hands with a soap invented by himself, which consists of domestic soap (one part), marble powder (three parts), and lysol (four per cent. of the whole). This soap is said to clean less

by chemical than by mechanical means, the fine marble powder penetrating into all the folds of the skin and rubbing away all dirt and detritus.—*Berlin Correspondent of Lancet.*

Average Duration of Life among Physicians.—A curious statistical record has been compiled by Dr. Salzmann, of Essling, Wurtemberg, on the average duration of life among physicians. He found, in going over the ancient records of the kingdom, that, in the sixteenth century the average duration of life among that class was but 36.5 years; in the seventeenth century, 45.8; in the eighteenth, 49.8; and at the present time they reach the favorable average of 56.7. It appears from the foot-notes to the above that this very great increase in longevity is due to the disappearance of the "Black Pest," the introduction of vaccination, and the great diminution in the number of typhus epidemics, three classes of diseases formerly the especial scourges of medical practitioners.

Journalistic Amenities.—At the banquet of the Mississippi Valley Medical Association we note among the toasts the following:

"The Medical Journalist"—Thou liar of the first magnitude.—*Congreve.*

Response—Dr. Frank P. Foster, Editor *New York Medical Journal.*

There is a kind of grewsome humor to this, which the distinguished editor evidently accepted with his usual good-nature. He described in his remarks with much eloquence the greatness of the Mississippi Valley and its Medical Association.

Further Medical Journalistic Amenities.—"To the pismire, whose weakness can arouse naught but a sneer, to the pale gray ass, whose offensive sounds loudly reverberate from his rear, to the gadfly buzzing around our editorial ear, we simply respond, Shoo fly, don't bother me."—*Medical Mirror.*

"Etis" or "Itis."—An unfortunate uncertainty obtains among the profession of this country as to the proper pronunciation of the large class of words whose termination is *—itis.* Many prefer the continental vocalizing of *i*, giving it the sound of English *ē*. The English profession and a very respectable portion of the American profession use the vowel *i* with its long English phonation—*ī*. There can be little doubt of the correctness of the usage of the latter group, so long as it is English we speak and not German or French. There is absolutely no authority for a continental vocalization of *i* in English speech, for if custom is pleaded in its favor, it is easily shown that custom is widely at variance, and that "*—ītis*" has more users than "*—ētis.*" Neither is there any uncertainty among the lexicons, whether medical or general, for with quite remarkable unanimity they give the English phonation. Expressing our sympathy for the adherents of the continental sound, we must needs leave them to their fate. —*Western Reserve Medical Journal.*

Treatment of Tuberculosis with the Blood-Serum of the Horse.—Dr. Paul Paquin, for many years Professor of Bacteriology in the State University at Columbia, Mo., and more recently member of the State Board of Health of Missouri, has been experimenting for some time upon the blood-serum of the horse as a remedy for tuberculosis. Demonstration satisfactory to himself having justified faith, and acting upon his belief that the horse is naturally immune against tuberculosis, he has been using for some months the blood-serum of selected horses, carefully injecting the serum underneath the skin of the victim of tuberculosis. He claims that the horse being naturally immune against consumption, the blood does not require artificial immunization, but can be used direct. About fifty cases have been experimented upon with almost universally satisfactory results. Dr Paquin has presented a detailed report of his work to the St. Louis Medical Society.—*Medical Mirror.*

A Man with a Big Heart.—Mr. A. J. Salmon died suddenly at Battersea, London, from a pudding indigestion. Autopsy showed that his heart weighed 21 pounds! —(*Temps.*) This must surely be a mistake. The heart weighs ordinarily about 10 ounces. It may hypertrophy up to 20 or even 40 ounces—but 20 pounds!

Public Hospitals.—The fancy on the part of physicians to erect public hospitals is one that seems to be growing. Dr. Lane, of San Francisco, has indulged himself in this way, and M. Henri Schneider has built and presented to the town of Creuzot, France, a hospital with accommodation for fifty beds.

An Anti-cigarette League, representing twenty-five thousand public-school boys in this city, has been organized.

The Communion-cup and the Homœopaths.—At the Forty-fourth Annual Meeting of the Homœopathic Medical Society of the State of New York, held in Albany, February 12th and 13th, it was

Resolved, This society is in full accord with the statement that the prevention of disease is preferable to its cure, and, believing that the adoption of sanitary methods tends to the prolongation of life and the prevention of disease, desires emphatically to place itself on record as being in perfect sympathy with the movement, now becoming widely spread, to dispense with the usual method of distributing the communion wine, and urges the speedy adoption of the individual-cup system, thereby avoiding the possibility of contracting many forms of infectious disease.

Barred Out of the Massachusetts Medical Society.—The Massachusetts Medical Society has voted to debar from its membership all graduates from the College of Physicians and Surgeons of Boston.

Reviews and Notices.

Atlas und Grundriss der Ophthalmoskopie und Ophthalmoskopischen Diagnostik. Mit 5 text- und 102 farbigen Abbildungen auf 64 Tafeln. Von Dr. O. Haab, Professor an der Universität und Direktor der Augenklinik in Zürich. München: Verlag von J. F. Lehmann. 1895.

In this small volume, one of a series of medical hand-atlases, we have a contribution to ophthalmoscopic diagnosis and pathology not less valuable than the large works of Jaeger and Liebreich. Being small, its

pictures cannot be judged by the same standard of fine quality which belongs to them. But their execution is really admirable, and the illustrations representing conditions nowhere else portrayed are not few. To the beginner as well as to the expert in ophthalmoscopy, the book will be most useful. Sixty-nine pages are devoted to description of the technique of the ophthalmoscope and its use, and to the appearances of the normal fundus oculi. The shadow test is adequately explained, not only in its method of use, but as to both its merits and its deficiencies.

The various appearances of the normal fundus are given in seven pictures, and if, in Fig. 3 a, the glittering reflex from the retina seems overdrawn, the attempt to show what sometimes is met with, will suggest the true explanation of an appearance which might be supposed to be a severe type of inflammation of the retina. The congenital anomalies are figured in eight pictures. It is proper to speak of seven sketches in Fig. 37, showing the senile alterations at the macula, which are by no means infrequent and are liable to be overlooked, leaving unexplained a serious loss of vision. A very interesting series of pictures, Figs. 38 to 45, shows the lesions due to blows upon the globe and to the entrance of foreign bodies. The white patches on the retina of only a few hours' duration, Figs. 39, 40, caused by direct blows (Berlin), have never before, the writer thinks, been depicted in color. That the presence of a small bit of iron adhering to the retina should occasion a lesion at the macula, when this locality has not been touched, is an observation not less important than novel. See Fig. 41.

In brief, this little atlas is a compact and admirable store of information. It is creditable to both author and publisher, and it is most agreeable to recognize that the high standard of ophthalmological teaching, which was so famous in Zürich during the lifetime of the lamented Horner, is being sustained by his successor.

Festigkeit der Menschlichen Gelenke, mit besondere Berücksightigung des Bandapparates. Habilitationsschrift für die Universität München. Von Dr. med. J. Fessler. München: M. Rieger'sche Buchhandlung. 1894.

This work contains the report of a series of experiments to test the strength of the human joints, that is, the power of resistance offered by their ligamentous structures. The values were obtained by means of three machines, one used for testing the traction-strength of wire, the other two being powerful levers. In the collaboration of a surgeon with a professor of physics we have a guarantee of the correctness of the results, which is but too often wanting in works of this kind.

The Physiology of the Carbohydrates: Their Application as Food and Relation to Diabetes. By F. W. Pavy, M.D., LL.D., FR.S., Fellow of the Royal College of Physicians; Consulting Physician to, and formerly Lecturer on Physiology and on the Practice of Medicine, at Guy's Hospital. London: J. & A. Churchill. 1894.

There seems to have been recently a revival of interest in the subject of glycosuria and of the whole question of carbohydrate metabolism, and this work by Dr. Pavy is therefore most timely. The author's views are known to all students of this subject through his former writings and utterances, and especially through the doctrines promulgated in his Croonian Lectures delivered last June. In this book the arguments in support of his theory are stated at length and the experiments from which they were deduced are described in detail and freely illustrated by micro-photographs. Dr. Pavy is known as the strongest opponent of the theory built up by Claude Bernard in his experiments, and he has here set forth most convincingly and interestingly the grounds for the faith that is in him.

A Manual of Diseases of the Ear, for the Use of Students and Practitioners. By Albert H. Buck, M.D., Clinical Professor of Diseases of the Ear, College of Physicians and Surgeons. Second edition. Pp. 457. New York: William Wood & Co. 1895.

In the present edition the distinguishing features of excellence are a new chapter on the analysis of symptoms, a desirable elaboration of the chapter on chronic purulent inflammation of the middle ear, while the section devoted to the description of operation on the mastoid process has been rewritten, elaborated, and profusely illustrated. All of which enhances its value as a text-book and maintains its well-won reputation as an authoritative treatise.

A Manual of Organic Materia Medica and Pharmacognosy. By Lucius E. Sayre, Dean of the School of Pharmacy, Professor of Materia Medica and Pharmacy in the University of Kansas, etc. Pp. xx., 555. Philadelphia: P. Blakiston, Son & Company. 1895.

In this substantial volume we find described the botanical and physical characteristics, source, constituents, and pharmacopœial preparation of the official, as well as of a large number of unofficial, drugs. The drugs derived from members of the animal kingdom also receive attention. The subject of pharmacal botany is discussed in the chapters devoted to morphology and to structural botany. In order that the student may understand the proper relationship of drugs, a two-fold classification is employed: 1, That of prominent characteristics, rhizomes, barks, cellular drugs, extractive substances, etc.; and 2, that of natural orders. In both classification to each drug is assigned the same number. This double classification is ingenious and facilitates reference. While an attempt to treat the subject of pharmacal botany in eighty-five pages necessarily results in a somewhat sketchy presentation, the author has accomplished his purpose of laying before the student the essential facts of botany. In the second part, although the pharmacopœial definitions are not followed, they are concise and, in general, excellent. The illustrations, nearly five hundred and fifty in number, are mostly from original drawings, and add greatly to the value of the book. Of especial interest are the appendices treating of insects injurious to drugs and of organic remedies formed by synthesis. In the latter appendix we recognize many old friends, and, as well, the newer acquisitions to materia medica. Their classification, as of the paraffin series, halogen derivatives, alcohols, ethers, esters, derived ureas, oxybenzoic acids, etc., is especially helpful, and tends to reduce to orderly precision the chaos which exists in the average mind when it attempts to understand the relationship of the numerous synthetic compounds. A third appendix is devoted to pharmacal microscopy, quite too brief, we believe it to be, and to a very satisfactory glossary of botanical and therapeutical terms. We have read this book critically, and we believe that the presentation of these subjects is a very satisfactory one and a faithful representation of the present existing knowledge which obtains in these closing years of the nineteenth century.

The Essentials of Homœopathic Therapeutics. By W. S. Dewey, M.D., Late Professor of Materia Medica, Hahnemann Hospital College of San Francisco, Cal., etc. Pp. vi., 266. Philadelphia: Boericke & Tafel. 1895.

This little book is a quiz-compend upon the application of homœopathic remedies to diseased states, and under chapter headings of diseases and symptoms are found the various symptoms and indication for the use of drugs. Doubtless the homœopathic practitioner will find this a very convenient book for reference.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting February 21, 1895.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Discussion on Amputations: A Statistical Study of Seven Hundred Cases from Eight Hospitals of New York City. Topics: Mortality, Gangrene of Flaps, Secondary Suture, Drainage, Dressings, etc.—The discussion was introduced by short papers upon the several topics named, by Drs. J. F. Erdmann, H. Lilienthal, F. Torek, P. R. Bolton, C. C. Carmalt, and S. Tousey.

DR. B. F. CURTIS, Chairman of the Section on Surgery, under whose auspices the meeting was held, said that the subject of amputations had been chosen for discussion in preference to abdominal surgery and some other topics, because of its more general practical importance. The original object had been to collect statistics of the city hospitals in their bearing upon primary union of amputation wounds, and union with or without sinus, and only incidentally upon the mortality-rate, etc.

DR. ERDMANN'S paper showed that of 703 amputations in eight city hospitals, forming the basis of his and the other papers, there had been a total mortality of 109, or 15.5 per cent. These were divided as follows: Of the wrist, 7 cases, no deaths; of the forearm, 74, with 1 death; of the elbow, 6, no deaths; of arm, 88, with 16 deaths; of the shoulder, 24, with 6 deaths; of the foot, 64, with 5 deaths; of the leg, 156, with 19 deaths; of the knee, 46, with 6 deaths; of the thigh, 223, with 48 deaths; of the hip, 18, with 8 deaths. The general mortality, therefore, was 15.5 per cent. In 31 cases death was due to general shock; 51, to septicæmia existing previous to the operation; 18, to constitutional causes; 27, to operative shock; 1, to secondary hemorrhage; 3, to sepsis following the operation; 3, to complicating nephritis or pneumonia; 1, to poisoning with bichloride. Under fresh or primary cases there were 270, with a mortality of 21.4 per cent.; non-primary or old injuries and disease, 433 cases, mortality of 11.7 per cent.

Dr. Erdmann then divided the cases into those operated upon between 1884 and 1889, and those operated upon between 1889 and 1894. The fresh traumatic cases showed an improvement in the mortality during the last period of five per cent.

These statistics were then compared with some given in *The Lancet* and with those reported in the MEDICAL RECORD recently by Dr. Estes. The great superiority of the latter was to be accounted for in part by the fact that they were in a degree select, and also by the younger age of the patients.

DR. HOWARD LILIENTHAL stated the results as to gangrene of the flap, by which was meant extensive sloughing or marginal necrosis. The latter, marginal necrosis, was not opposed to good surgery. Of 367 cases where the flaps consisted of skin alone, 69, or nineteen per cent., sloughed in whole or in part, while of 216 cases of musculo-cutaneous flap, only 41 sloughed, or nineteen per cent.—showing the comparative advantage of the musculo-cutaneous flap as to vitality. The skin flap was also found to be more easily killed by sepsis. The statistics showed further that constitutional disease was a frequent cause of flap necrosis. Great judgment was required in deciding as to the viability of tissues through which amputation was done. The tendency to flap gangrene was greatest below the knee. Musculo-cutaneous flap was to be selected wherever possible.

DR. TOREK had found that out of the 703 cases secondary suture had been employed in 37; in 20 of them the wound was closed in forty-eight hours; in 17 later. The former were termed early secondary suture, the latter late secondary suture. In none of the 37 had there been death; primary union in 17, or forty-five per cent. Seventy-eight per cent. united; twenty-two per cent. did not. Late secondary suture had not given as good results as early secondary suture, for reasons not far to see. Primary union depended mainly on two factors—proper adaptation of the parts and asepsis. When the flaps had granulated for some time, they were not so likely to be aseptic nor to permit of accurate adaptation. While the ideal method would be immediate adaptation of the flaps without drainage, yet where the chances of primary union were in the least degree doubtful, Dr. Torek thought better results would be obtained by secondary suture.

DR. P. R. BOLTON, writing of drainage and dressings, said that the only purpose which drainage could serve in an aseptic wound was to remove serum and blood. It seemed that this purpose could be served by proper suture and dressing. Where, however, there was infection, drainage would continue to serve an important purpose. In the statistics given, of 490 cases treated by suture and drainage, 167 healed by primary union; 128 by primary union with sinus; 195 by granulation with more or less suppuration of the flap. Of 142 amputations of the upper extremities, 72.5 per cent. healed by first intention; of 348 of the lower extremities, fifty-five per cent. healed by primary union; seventy per cent. of those of the hip; sixty per cent. of those of the thigh; forty-three per cent. of those of the knee and leg; forty-six per cent. of those of the foot. Of 56 cases treated with suture without drainage, 34 healed by first intention, 8 by first intention with sinus, and 14 with granulation.

The question of whether drainage should or should not be employed must be decided in most cases by the disease or injury for which amputation was performed. It could be dispensed with in many cases of amputation for tumor, also in some cases of joint disease, trauma, etc.

DR. C. C. CARMALT had found details with regard to the duration of the treatment in only sixty of the cases. The average stay in the hospital had been forty-two days. But this was of little significance without taking into consideration the environments, general condition of the patient, condition of field of operation, and the after-treatment. In two of the sixty the duration in the hospital after amputation had been one hundred days. In none of the sixty cases had there been primary union. The younger subjects went out earlier. Hemorrhage and shock had apparently had no influence on the duration of treatment. There was delay in all cases where there had been other diseases or exhaustion. This remark did not apply to disease of the heart or kidneys, syphilis, or vascular changes, except thrombosis in one instance.

DR. S. TOUSEY read regarding shock and other points, basing his remarks upon 181 of the cases which were observed at Roosevelt Hospital. In amputations for traumatism, in cases in which the primary shock was marked, the mortality had been forty per cent.; where it was absent, the mortality had been only five per cent. The inference was that the shock from the injury killed the patient. If the shock were slight or absent, the condition of the nerves of the limb from the traumatism was one of paralysis, and amputation did not act to produce more shock, as was seen where the shock of the operation alone had added to the mortality only five per cent., whereas the original shock increased by the shock of the operation increased the mortality very greatly. Dr. Tousey thought the operation should be done before this paralysis of the nerves had been recovered from. The statistics showed that where the shock had been treated more than twelve hours prior to amputation there had been sixty-six per cent. of deaths, against twenty-two per cent. of deaths

in cases with shock of like degree, but treated only three or four hours before amputating.

The other subject which he had studied at Roosevelt was the circumstances affecting the frequency and duration of sinuses. Age had little to do with it, while the site of the amputation had a great deal to do with it. Sinuses occurred oftenest in amputations of the upper extremities, especially at the shoulder, but the duration was greater in the case of the lower extremities, and greatest of all in the foot. It made little difference in the duration whether bone-tube or rubber-tube were used for drainage, the advantage being a little on the side of rubber. The age of the patient had much to do with the mortality.

General Discussion.—Dr. Charles McBurney was asked to open the general discussion. The subject, he said, was too vast to attempt to cover it in a systematic manner. Therefore, he would refer only to a few points suggested by the papers. He thought the mortality at present would be much smaller compared with that of ten years ago, if amputation were done as frequently. With improved antisepsis, etc., surgeons now tried to save many limbs severely injured, which some years ago would have been sacrificed at once.

The speaker seldom saw gangrene of the flap. It was not infrequently due to bruising and injury inflicted by the operator, especially when the flap consisted of skin alone. Particular attention should be given to the condition of the circulation at the proposed point of amputation. If it were in a doubtful state, amputate higher. If the foot were gangrenous one could easily tell whether it were safe to amputate at a given point by making a transverse incision and observing whether hemorrhage followed. If not, the circulation at that point was poor, and one should go higher.

Dr. McBurney was in accord with what had been said with regard to the value of secondary suture in decreasing the mortality. He would include it under the head of drainage. The only objection to drainage consisted in leaving it too long. If the wound were aseptic, the tube ought certainly not to be left in longer than forty-eight hours, probably not longer than twenty-four hours. Much could be said with regard to shock. A loosely attached limb could be snipped off with the scissors, the wound treated by open tampon, the patient allowed to go without further traumatism until shock was recovered from, secondary amputation being done later. He had saved several patients by pursuing this course when primary amputation would probably have ended fatally.

In the speaker's opinion, many cases of shock, so called, were cases of hemorrhage. The amount of blood lost was a matter of very great importance, and one should, at a very early period, make use of active measures to overcome its bad effect. For this purpose he had found of greatest value hot saline solution thrown into the blood-vessels. The infusion might be made before, during, or after amputation. A quart or quart and a half of normal salt solution could thus be injected.

Point for Amputation Determined by Esmarch's Bandage.—Dr. L. A. Stimson thought it not unlikely that the greater mortality attributed by one of the speakers to waiting twelve hours or longer on account of shock was due, not to the waiting, but rather to presumably greater severity of the injury in those cases. He had been taught by Dr. Van Buren not to amputate during shock; that amputation would be safe as soon as the temperature began to rise again from subnormal. We owed much to Dr. McBurney for calling attention to the value of injections of saline solution. Regarding necrosis of flaps, he had seen many cases at the Chambers Street Hospital and elsewhere in which doubt existed as to the vitality of parts through which it was proposed to amputate, and he had found the best means for determining that point to be the application of the Esmarch bandage three to five minutes. After its removal there would be a blush in the blanched healthy skin not seen in the diseased or non-vital portion. Follow the outline of the parts which had been white. The knife should be carried down close to the fascia in all skin flaps, as it increased the chances of survival of the flap. Loose suture and snug bandage would give all drainage required in most cases, thus doing away with the drainage-tube and with the necessity for change of dressing called for by other plans.

Dr. Robert Abbe emphasized a few points, the first being the importance of using muscle and skin flaps instead of skin alone wherever possible. The skin flap sloughed because of tendency to fall in folds and because of pressure on harder parts. Another point was the value of deep-buried suture in muscle over the end of the bone. Regarding drainage, he had been surprised that so much had been said about sinuses resulting. There might be a little sinus for a while, but this was unimportant, while drainage was very essential. As to gangrene, it was apt to occur in amputations through the foot, because bone immediately underlay skin, whereas, in amputations where muscle as well as skin and subcutaneous tissue overlay the bone, there was better nutrition. Besides, amputations through the middle of the foot did not leave a serviceable limb because of painful scars, etc., and it was better to cut through the lower third of the leg if possible, or through the lower third of the thigh, points at which instrument-makers found it possible to apply the most serviceable artificial limb. Amputation through the lower third of the leg was to be preferred even to Symes's amputation, although this gave an admirably bearing stump. He thought shock was due largely to hemorrhage.

Dr. F. H. Markoe thought the cases divided themselves into two classes naturally—amputation for traumatism and amputation for disease; again, into amputation for septic conditions and for non-septic conditions. In non-septic conditions amputation should be done through healthy tissues and the wound closed. By using buried suture, accurate apposition, and careful dressing, he had had no occasion to regret omitting drainage. In traumatic cases he agreed with Dr. McBurney that we should cut away waste tissue and wait until after shock had passed before amputating. In certain of the remaining cases gauze drainage might be used twelve to thirty-six hours, and in the others secondary suture and tamponade.

Dr. F. W. Murray thought it had been definitely shown that since the introduction of antiseptic surgery the mortality from amputations had been decreased, and it was destined to be decreased still further. He always drained the first twenty-four or forty-eight hours. He had great faith in secondary suture in certain cases. He, too, had had opportunity to save the lives of several patients by hot saline infusion. It was very necessary in amputations to shorten anæsthesia as much as possible, and this was one important reason for using tamponade and secondary suture.

Drainage or no Drainage.—Dr. B. F. Curtis said it had been hoped to show the comparative advantage of drainage and no drainage in amputations, but a fair conclusion could hardly be drawn from the statistics given, since drainage had been practised in over five hundred cases and omitted in only about fifty. With drainage there had been absolute primary union in thirty-seven per cent. of the cases of amputation of the upper extremity, thirty-three per cent. of the inferior extremity, or thirty-four per cent. altogether; and primary union including sinus in seventy-two per cent. of the upper extremity, fifty-five per cent. of the lower extremity, or sixty per cent. altogether. Against this, without drainage there had been absolute primary union in sixty per cent. of amputations of the upper extremity, seventy-one per cent. of the lower extremity, altogether sixty-seven per cent.; and primary union including sinus, in seventy-three per cent. of amputations of the

upper extremity, seventy-seven per cent. of the lower extremity, or seventy-six per cent. altogether.

Dr. Curtis thought New York surgeons did not appreciate as much as they should the advantage of getting rid of drainage, since it would exclude danger of introducing sepsis with the drain, and again with the second dressing. While a sinus, usually due to the drain, might not be serious, yet it was very disagreeable, and kept the patient in the hospital for days when the space was desired for new patients. One cause of gangrene of the flaps had been cutting them too short, so that there was tension on the sutures which held them over the ends of bones. He did not think all would agree with Dr. Abbe in his condemnation of amputations through the foot, especially in workingmen, who could not meet the expense of renewing costly artificial legs.

There should be improved methods of keeping records of cases in our hospitals. Some important details were lacking in these statistics.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, February 18, 1895.

S. B. W. McLeod, M.D., President, in the Chair.

Annual Address by the President.—Dr. McLeod chose for the subject of his address, "The Place and Influence of the Medical Profession in the Progress of Civilization." His remarks referred not alone to members of the profession, but equally to many outside the profession who had done much to further its efforts in elevating the human race. Among these were Benjamin Franklin, Stephen Girard, the Vanderbilts, and many others. It was not easy to define the word civilization. While in its full sense it meant advancement, yet it was attended by certain disadvantages unknown in the savage or uncivilized state. Some of these were the accidents attending the introduction of the industrial arts. The profession was called upon to treat the injuries resulting from railway travel, to cope with the spread of contagious diseases through modern facilities for travel. The organization of a meteorological bureau and the establishing of boards of health were features of modern civilization, and promised much for the promotion of human health and happiness. The question might well be asked, what next should engage our attention, and how with our improved means were we to meet our present responsibilities?

A few of the many questions of lively interest were, the eradication of tuberculosis; prevention of spread of disease in schools; greater widening of the field of usefulness of orthopedics; the further perfection of electro-therapeutics; prevention and treatment of ophthalmia neonatorum; should criminals by heredity be unsexed; improvement in relation to expert testimony.

Dr. McLeod referred also to the prosperous condition of the Association, and said it was a duty and a pleasure to enter upon the new year with energy and determination in the purpose to consider such subjects as were practical and calculated to improve the profession and promote the public health. The great work accomplished by the late Dr. William Detmold, the first president of the Association, was placed before the members, young and old, as a most worthy example.

The Neuroses of Women.—Dr. T. J. McGillicuddy read a portion of a long paper which he had prepared on this subject. Every woman, he said, suffered more or less, and many almost constantly, from functional derangements of some of the organic structures of the body. Many simple deviations from the normal were really precursors of conditions of a most serious nature. But calling them minor ailments, there was still every reason to investigate them, because of their great frequency and the important bearing which they had upon our success as practitioners. Our first duty was that of healing, and not altogether that of trying to solve scientific problems. Old ladies and lay persons generally were loud in their praises of irregular practitioners, simply because they had given attention to their minor ailments.

Among the more important of these lesser derangements were the reflex neuroses. Some seemed to consider them insignificant, and some even appeared to doubt their actual existence. By the generic term neurosis was meant a hyperæsthesia or disturbance of the nervous system which simulated disease in an organ that was healthy, or without evident lesion of any of its parts. It might be general or local. The specialist who saw such patients must have the knowledge of the general practitioner, otherwise many mistakes would be made in diagnosis and treatment of chronic ailments. If the confiding and unsuspecting patient with a run-down constitution, the result of anxiety, bad air, and a worse diet, and with a headache and some abdominal or uterine symptoms, should stray into the office of an enthusiast in ocular tenotomy, he would probably want to relieve her distress by dividing the rectus muscle for eye-strain. If, however, she should strike a surgical gynecologist of a certain class, a symptomatic uterine catarrh, an unoffending laceration, or a harmless, retiring cystic ovary would be pounced upon by this enlightened specialist, and receive most vigorous treatment; and if he did not always carefully sterilize his instruments he would probably succeed in sterilizing his patient. Or her destiny might lead her into the office of a digestive specialist, who, of course, would diagnose stomach trouble as the cause of all her ills, and proceed to lower several feet of rubber hose into her surprised stomach and treat that organ to a wholesome bath. If our specialism was allowed to run into exclusivism, very shortly the only safe man for a patient to consult would be the old-fashioned general practitioner, with all his faults and deficiencies.

There was much difference of opinion with regard to the causation of the various neuroses, but many cases had been recorded illustrating the fact that peripheral irritation was a very decided factor in their production. Irritation might be set up in any part of the body, and result in a reflex disorder in a distant organ. Some of the sources of irritation which might be noted were: The digestive organs—indigestion; *a*, stomach—gastric catarrh; *b*, intestines—parasites, ulcers; *c*, rectum — hæmorrhoids, thread worms, pruritus ani. The genito-urinary organs—inflammations, internal; *a*, kidneys—calculus; *b*, bladder — calculus, catarrhal states; *c*, ovaries—inflammation, morbid growths; *d*, uterus—inflammation, morbid growths. External; *a*, vulva—pruritus, herpes; *b*, clitoris—adhesions. The respiratory organs—inflammation, irritation (catarrh), new-growths—the eyes—eye-strain, errors of refraction and accommodation. The ears — abscess, impacted cerumen.

This, the author said, was by no means a complete summary of the causative factors which operated in the production of reflex disturbances, yet they were fair examples of what we should look for when searching for some peripheral irritation to assist us in the diagnosis and treatment of disease.

Strong mental impressions stimulated the vesical and rectal nerves of the young soldier when going to battle for the first time; the uterine nerves in the young female emigrant produced amenorrhœa, from the excitement incident to leaving home and going to a new country. The differential diagnosis between a severe reflex headache depending upon uterine or digestive trouble, and beginning exophthalmic goitre where a

rapid pulse and swollen thyroid were among the earliest manifestations, was often exceedingly difficult, as the mere fact of entering a physician's office for examination would often produce in nervous young women a great amount of excitability, giving rise not only to a rapid pulse, but also globus hystericus and temporary congestion of the thyroid.

The following classification of the neuroses suggested itself: The neuroses of the nervous system; of the circulatory system; the respiratory system; the genito-urinary system; the glandular system; the cutaneous system. The spinal and cerebral centres were not alone implicated, but the ganglionic and vasomotor nerves probably even more. The cardiac and solar plexuses in particular, took an important part. A further division of the neuroses with regard to the parts affected might be made as follows: cerebral, spinal, cardiac, vascular, pharyngeal, laryngeal, bronchial, gastric, intestinal, renal, vesical, genital, glandular, ophthalmic, aural, lingual, articular, dermal. Many of these were combined, as in the cerebro-spinal, gastro-intestinal; while two or more might exist at the same time, as vascular and glandular.

The author had time to read further only about the cerebral neuroses or psychoses. Among peculiar mental conditions depending upon morbid conditions of the abdominal and pelvic viscera, were: mental depression; loss of memory; excessive irritability; wakefulness; intense lethargy and drowsiness during the day; morbid fears, as of death. Under the head of cerebral psychoses fell catalepsy, trance, hypnotism, somnambulism, neurasthenia, anæsthesias, amenorrhœa, enuresis, dyspepsia, and diarrhœa coming on from bad news or "hard times." Also all the hysterical symptoms depending upon the emotions, such as hysterical aphonia, hysterical apnœa, hysterical laryngismus, hysterical suffocation and strangulation. More severe types were melancholia, mania, and convulsions.

The cerebral neuroses often occurred in neurotics from the mind being directed to a particular part. This was seen in patients who were familiarly known as "womb cranks," who imagined they had uterine disease, and were sometimes readily cured by almost any simple manipulation of the uterus.

The author related a case of migraine, hemiplegia, and chorea depending upon uterine irritation. The symptoms came on after an attack of diphtheria, but as she had suffered from disordered menstruation and hysterical symptoms, and the hemiplegia disappeared from the left side and later appeared on the right, it was evidently of a hysterical nature, starting, with her other hysterical symptoms, from pelvic disturbance. Like chorea—which was also present in this case—functional hemiplegia was found during periods of development.

Diagrams were shown.

Melancholia due to Uterine Retroflexion.—Dr. H. J. Boldt thought the paper was so complete that nothing remained to do but relate cases in corroboration. He recalled the case of a woman who had suffered from profound melancholia with suicidal tendency, due entirely to retro-displacement of the uterus. There was relief after replacement of the womb, but subsequently it again became displaced, melancholia returned, and again disappeared on the insertion of a pessary. Tachycardia was common in backward displacements of the uterus.

Dr. Boldt, and some of the speakers who followed him, emphasized the author's remarks upon the necessity for a knowledge of general medicine before practising a specialty, and cautioned against the recognition of but one part of the human frame, that which happened to correspond to one's speciality.

Dr. Frederick Peterson, having arrived in time to hear only the latter part of the paper, remarked simply upon a study of the entire system, and cautioned against unduly magnifying any of the organs in the production of neuroses or psychoses. For instance, he believed that in connection with gynecology there had been a tendency to attach too much importance to conditions of the uterus and ovaries in the causation of neuroses. An experience of two or three years in an asylum had convinced him of the correctness of this view.

Dr. Nathan G. Bozeman mentioned a case of enuresis in which it was possible to make very accurate observations, since the woman had a vesico-vaginal fistula. She was suffering from an irritable condition of the organs of the pelvis, which was not relieved by the treatment which a physician, who had previously seen her, had directed to the uterus. On one occasion the urine was collected every hour for thirteen hours. During the first twelve hours she passed only one ounce of urine, while the next hour she passed fifteen ounces.

Dr. Achilles Rose mentioned as an example of the influence of emotion on the gastro-intestinal functions, the fact that, as Napoleon's army was going through Poland in 1812, all the soldiers had dysentery from drinking stagnant water, but the dysentery ceased during a battle of three days' duration, and returned at its close.

Dr. J. Blake White emphasized the statement that one should practice general medicine before entering upon a specialty.

Dr. Leonard Landes pointed out the difference between exophthalmic goitre and myxœdema as described by German and French writers, having mistakenly understood the reader of the paper to say they did not differ.

Dr. Brothers said a word as to the treatment of neuroses, and particularly of the necessity for checking sexual excesses and errors of diet, which were among the most potent causes. Calisthenics should be practised. Arsenic occupied about the first place among drugs.

Dr. Frank Van Fleet thought there had to be an idiosyncrasy, else patients with uterine disease, ocular trouble, etc., would not suffer from reflex neuroses. When that idiosyncrasy did exist, he thought the exciting cause was no more likely to be in the uterus than in the eye or other organs, and it might be necessary to send the patient to several specialists before relief could be given.

Dr. McGillicuddy, in some concluding remarks, said he thought general practitioners should know enough about medicine to treat the neuroses without sending the patients to specialists.

Paroxysmal Hæmoglobinuria.—Dr. Bishop reported a case in which the urine on certain occasions contained blood-pigment, but which upon careful and repeated examination had not been found to contain blood. The patient was a sailor, and had begun to pass colored urine from the time of great exposure on shipboard. He could bring on an attack at will by exposing himself to the cold, and it was only after exposure to cold that the urine was colored. In the summer he had attacks—apparently replacing the paroxysmal attacks of hæmoglobinuria—of cerebral symptoms coming on at night, during which there was fright, especially fear of being enclosed in a small space, as a barrel. Dr. Bishop had advised the patient to take up his residence in a warm climate, but such advice, he said, might prove disastrous should the cerebral symptoms become more frequent in the absence of attacks of hæmoglobinuria.

A New Diagnostic Sign of Carcinoma of the Stomach consists, according to Boas, confirmed by Dr. D. Stewart (*Medical News*) in the presence of lactic acid. By giving a test-meal (flour soup) quite free from any lactic acid this acid was never found in any conditions except those of carcinoma.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 23, 1895.

GEORGE P. BIGGS, M.D., PRESIDENT.

Primary Tuberculosis.—DR. E. HODENPYL presented three specimens of tuberculosis, illustrating some rare conditions. The first one was from a case of primary tuberculosis, with volvulus and perforation of the intestine. He was indebted for this specimen to Dr. Sanger, house physician of St. Francis Hospital. The patient was a fairly nourished man, forty-five years of age, a baker by occupation, who gave a history of the bowels not having moved for two weeks previous to his coming to the hospital. On admission, the abdomen was distended, and his temperature was 99°. A large dose of calomel failed to relieve the constipation, and on the following day several enemata were given without result. After this he was given a large dose of croton oil with negative result. The temperature then rose, an intense peritonitis developed, and he finally died. The autopsy showed a general peritonitis, and at about two feet from the ileo-cæcal valve a volvulus which completely constricted the intestine. Above this point the intestines were considerably distended. Here there were also two perforations of the intestine, and another perforation was found below the point of constriction. The intestines were covered with a rather large number of tubercular ulcers. Microscopical examination confirmed the diagnosis of tuberculosis of the intestine.

The speaker said that this was the first case of primary intestinal tuberculosis he had met with, and so far as he could ascertain none of his medical friends had seen such a case. There was nothing in the history to give a clew as to how he had contracted the disease, and there were no evidences of tuberculosis in other parts of the body than the intestine.

Healing Tubercular Ulcers of the Colon.—The second specimen presented had been removed from a man who had suffered for a number of years from pulmonary phthisis. In the small intestine were a moderate number of small tubercular ulcers, while in the colon there were a number of ulcers with irregular margins and smooth bases. Microscopical examination of these ulcers showed some remnants of tubercular disease, but the bases were covered with new connective tissue. It was certainly rare to find a case in which tubercular ulcers of the intestine were healing.

Tuberculosis of the Bladder.—The third specimen was more interesting from a clinical standpoint than from a pathological one. The specimen had been taken from an old consumptive, who had been in the hospital for three months before his death, and yet no bladder symptoms had been detected.

The autopsy showed advanced tuberculosis of the lungs and two or three small tubercular abscesses in the kidney. The bladder was quite small and contracted. In the fundus were a number of irregular ulcers, and toward the edge a few miliary tubercles. Section of the walls of the bladder showed tuberculosis and considerable round-cell infiltration.

DR. WILLIAM VISSMAN asked if in the second case the patient had been treated with tuberculin, as the condition in the intestine was very much like that found in patients who had been treated with tuberculin shortly after its first introduction.

DR. HODENPYL said that he did not know how the patient had been treated.

THE PRESIDENT said that the specimen recalled to his mind one recently added to the museum of the New York Hospital, the clinical history of which he did not for the moment recall. There were characteristic tubercular ulcers presenting distinct evidence of attempts at repair.

DR. SAMUEL ALEXANDER, referring to the third specimen, said that the position of the ulcer, so high up in the fundus of the bladder, was a very unusual feature, without any ulceration in the trigone. If we were to hold to the theory that tuberculosis of the bladder was due to an extension from the urinary tract below, usually beginning in the seminal vesicles or the prostate, it would seem strange that the bladder should escape so completely. Such a condition, he thought, was almost unknown among clinicians.

DR. HODENPYL asked if Dr. Alexander had found in his experience that tuberculosis of the bladder was usually attended with great pain.

DR. ALEXANDER replied in the affirmative.

Urethral Stricture, Cystitis, Suppurative Nephritis.—DR. FARQUHAR FERGUSON presented the bladder, urethra, and kidneys from a male, fifty-six years of age, who was admitted to the service of Dr. L. A. Stimson on January 17th. He had had gonorrhœa twelve years before. During the past five years there had been difficult micturition; the stream of urine had been small, and the urine had contained mucus and pus. He had been obliged to get up several times during the night, the pain being greater at night and when the bladder was full. During the three weeks prior to his admission to the hospital he had had more pain, micturition had been more frequent and difficult, and the urine had contained both blood and pus. At the time of his entering the hospital the urine was dribbling away constantly. Dr. Stimson performed supra-pubic cystotomy under cocaine anæsthesia, and the bladder was continuously irrigated. After the operation the urine had a specific gravity of 1.010, contained five per cent. of albumin, and the microscope showed numerous pus-cells. Although the bladder was constantly irrigated, the patient's condition steadily grew worse, and he finally died on January 21st. At the autopsy, the supra-pubic incision was found to communicate with the bladder through an opening 1½ ctm. in diameter. In the perinæum were three sinuses leading toward the urethra. After the removal of the bladder it was found that the sinuses communicated directly with the membranous portion of the urethra. At the junction of the membranous and penile portions of the urethra was a tight stricture. In front of the stricture the canal was narrowed and its wall thickened for a distance of five centimetres. This portion presented evidence of previous inflammation. Behind the stricture the urethra was greatly dilated, dark in color, and necrotic. The wall of the bladder was greatly thickened, and in its walls were numerous pouches containing pus. These varied in capacity from one to fifty cubic centimetres. The mucosa of the bladder was softened and discolored. A probe two millimetres in diameter passed through the stricture. The pelvis of each kidney was dilated, and the left kidney contained numerous purulent foci.

Purulent Pericarditis.—Dr. Ferguson also presented a remarkable specimen of purulent pericarditis. The patient was a male, twenty-two years of age, who had been admitted to the hospital on January 7, 1895. He had previously had two attacks of la grippe, and was an alcoholic subject. Five days previously his illness had begun with severe pain in the right side and in both knees, an aching in the lumbar region posteriorly, and dyspnœa. He had not had a chill or cough, nor had he been very feverish. He had had no headache, and had not been aware of any heart trouble. His dyspnœa had grown steadily worse. On admission, his pulse was 122, respirations 48, and temperature, 100.8° F. Physical examination showed friction sounds in both axillæ, and abundant sibilant and sonorous rhonchi scattered over both sides of the chest. There was dulness at both bases posteriorly, and also diminished respiratory murmur. Just below the spine of the right scapula was an area of diminished resonance, and over this portion were distant bronchial voice and breathing. Respiration was labored and rapid. The cardiac area appeared to be normal. The first sound of the heart was somewhat valvular and

feeble, and the heart action was rapid, regular, feeble, and occasionally intermittent. The other organs were normal. The urine had a specific gravity of 1.020, but was normal except for a trace of albumin. During the next seven days he was given stimulants freely, and was cupped over the chest several times, but without improvement. His cough increased until it became very distressing. The temperature varied between 101° and 102°. On January 15th he was discovered to have pericarditis, and three days later he died very suddenly. The autopsy was made five hours after death. The lower part of the upper lobe of the right lung presented the appearance of red and gray hepatization, and there was no evidence of resolution. The entire lung was poorly aërated, and was congested and œdematous. The left lung was also poorly aërated, and showed the effects of pressure by the fluid in the pericardium. The pericardium, which was enormously distended and thicker than normal, contained in its cavity 2600 cc. of pus and fibrin. Its inner surface was quite rough and was covered with fibrin. The visceral pericardium was also covered with fibrin, and on removing this fibrin the pericardium underneath was seen to be intensely congested. The heart showed the effects of pressure, being crowded upward and backward. On separating the right lung from the pericardium an area of lymph three centimetres in diameter was found between the pneumonic area in the lung and the pericardium, which at this point was involved so that microscopical sections showed the entire depth of the pericardium to be the seat of inflammation, from the lymph outside to the endothelium. Examination of the pus and cultures from it showed Fraenkel's diplococcus in vast numbers.

Dr. S. T. Armstrong said that Dr. John B. Roberts, in his monograph on "Paracentesis Pericardii," had cited a number of instances in which he had tapped the pericardium, and had recommended irrigation where the cavity contained septic material. The speaker said that he had tapped pericardia where there had been much less distention than in the case just reported, and he had at present in the hospital a patient who had been tapped two years ago, and had done well since then. Another and rather radical operation had been recommended—that of trephining a rib, stitching the pericardium to the chest-wall, and irrigating.

The President said that in the case reported by Dr. Ferguson the house staff had been afraid to tap, as the pneumonia had been thought to be more extensive, and as the respiratory sounds had been heard quite far forward, it was not thought during life that the distention of the pericardium was anything like so great. It would be seen from the specimens that both lungs overlapped the pericardium, and were adherent to it, so that while there was dulness, the respiratory sounds extended far over.

The Society then went into executive session.

Aseptic Hands.—Reinicke, in Zweifel's clinic, has been studying the various methods recommended for cleaning the hands before operation. He used two cultures, one of a very resistant potato bacillus, and the other of the bacillus pyocyaneus. These he rubbed on his hands, allowed to dry for one hour, and then tried to wash off, using all his solutions as hot as could be endured. Water, soap, and brush, 3 to 5 per cent. carbolic solution, 1 per cent. bichloride solution, failed to sterilize the hands; but after brushing them five minutes with absolute alcohol, and then rinsing in sterilized water, they were perfectly microbe-free. He thinks some of the effects must be due to the fat-dissolving power of the alcohol, as he considers its bactericidal power very slight.—*Berliner klinische Wochenschrift*, December 3, 1894.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE COLD WAVE OVER ENGLAND—EFFECTS ON DISEASE AND MORTALITY—APPEAL FOR ST. THOMAS'S HOSPITAL—THE COLLEGE OF SURGEONS—THE HUNTERIAN CELEBRATIONS—MEDICAL, CLINICAL, AND MEDICO-CHIRURGICAL SOCIETIES—CASES—ÆGOPHONY—SPECIAL DISCUSSION ANNOUNCED ON SYPHILIS.

London, February 16, 1895.

Another week of bitter cold winds, severe frost, and snow makes the weather still the uppermost subject of even strictly medical news. It is many years since we have suffered such a hard month. In New York you might not regard it as phenomenal, for you enjoy (?) greater extremes of temperature than we are accustomed to; so we are not prepared for them.

Our œdiles, too, are "feeble folk"—a touch of frost or a fall of snow paralyzes them. It's a pity we cannot exile them to Paris or further, just to learn their business. The newspapers, too, are so busy reporting deaths from cold, frozen animals, skating items, snowed-up trains, and other hindrances to traffic and movement, that they have no time to drive home the lessons of hygiene and government which ought to be enforced by the chronicle of disaster. Could anything be more pathetic than to read of hale drivers frozen to death on their rounds, or the wild deer coming from their forests to share with man the warmth of an engine fire?

The sight of hundreds of sea-gulls that have found their way to London may now be witnessed on the Thames Embankment, and numerous are the men and women who go to see and throw food to the poor, half-starved birds which scramble for the fragments thrown to them. The effect on the mortality will yet be seen, and we know the returns will show a great increase in the deaths of the very young and the very old.

Some of the mains of the water companies are frozen, and because we have handed over a monopoly to these companies their servants do nothing to help their customers, and in some instances insult applicants for the water they have contracted to provide. It is a strange sight, in even aristocratic quarters, to see a single standpipe erected in a street, and the servants of the houses fetching pails of water, while thousands of men are unemployed and would be glad if the companies would engage them to carry the water and fill the household cisterns. Take this as an example—there is a house paying £20 a year for water, and the company is not fulfilling its contract. A very little expense incurred would enable it to do so. Surely it is time for Parliament to step in and declare the monopoly forfeited.

On Wednesday the Duke of Connaught presided at a meeting at the Mansion House, called to appeal for £100,000 for St. Thomas's Hospital. No doubt the charitable public will respond. Indeed it would be sad if they did not, for though there may be room for criticism and possibly reform in the management, St. Thomas's is a great hospital, doing a great work, and the demands on its resources are growing while those resources are diminishing.

The Council of the College of Surgeons have passed a resolution that, in accordance with their legal adviser, it is not expedient to accede to the resolution of the Fellows at their January meeting. Just as I predicted, the members' society is now in working order, but what it will accomplish remains to be seen. The Government has promised not to grant the increased judicial powers asked for by the Council until the members have been heard in opposition. If the members' society has sufficient tact something may be obtained from this decision.

The College yesterday (14th) kept Hunter's day, as usual, by the Hunterian oration, which was delivered this year by the President, Mr. J. W. Hulke, and will rank with its predecessors. I cannot do justice to it in the few lines at my disposal—nor yet to another oration delivered in honor of Hunter—that at the society named after the illustrious surgeon. This was given the previous evening, so as not to clash with that at the College. It was entrusted to Dr. Patrick Manson, who gave a demonstration of the malaria parasite in connection with which you will recognize his great authority. I must defer any account of these two celebrations and pass on to record that those who ventured out to the societies during this bitter week have been rewarded by some interesting cases on two clinical evenings—one at the Medical Society, on Monday, when nearly a dozen patients were exhibited; the other at the Clinical Society, on the previous Friday, when fully as many patients were presented. Here also a bottle of green urine was shown passed by a child early one morning. It had been noticed sucking some blue cloth the evening before. This cloth was dyed with indigo, which seems to have combined with the yellow coloring matter of the urine to strike green, an interesting object-lesson as to unusual appearances.

On Tuesday the ordinary meeting of the Medico-Chirurgical Society was devoted to Ægophony. Dr. F. Taylor read a paper on the causation of this symptom, which he attributed to a dissonance or musical discord—the result of beats occurring between the higher harmonies of the note uttered by the patients. The hypothesis was elaborated with some care, but did not meet with full acceptance. If not discord, it at least produced some dissonance; one Fellow remarking that the author had confused musical discord with an unpleasant noise, which is only a popular idea of discord. Another said it was no question of harmonics, but only a confusion of tones of different timbre, though of the same pitch. As the symptom is of little clinical importance, its causation is only an academical question, and the discussion hardly deserves further notice.

I have already announced that special discussions will be held in future at this Society. The first of these is to be opened on the 26th, by Mr. Hutchinson, "On Affections of the Nervous System Occurring in the Early (Secondary) Stages of Syphilis." A number of eminent men have already been asked to take part in this discussion, which appears likely to be vigorously sustained. Perhaps it will bring to light new facts as well as stimulate criticism.

THE PNEUMOCOCCUS AND IMMUNITY DISCUSSION AT THE PATHOLOGICAL SOCIETY OF LONDON.

(Special Report by our London Correspondent.)

An important meeting of the Pathological Society was held on February 5th, when Dr. Washbourn described his researches on the pneumococcus, with especial reference to immunity. After stating the results of others, he gave some account of his own extensive experience in the case of rabbits. Intra-peritoneal and subcutaneous inoculation were both used. Peritonitis generally ensued after the former; sometimes, with very virulent cultivations no peritonitis was noticed, although the animals died from general infection. Sometimes an animal died from marasmus a long time after inoculation. No cocci are then found in the blood, but in some cases there was a parenchymatous nephritis. The course of the fever, and the occurrence of cocci in the blood after inoculation were stated in full. When the temperature began to fall, then the blood was crowded with cocci. Of the various means of producing immunity, Dr. Washbourn had generally used that of G. and F. Klemperer, by previous injection with heated broth cultivation. The immunity did not occur till twenty-one days after injection, and disappeared after the thirty-first day. Dr. Washbourn quoted a number of experiments showing that the blood-serum, when injected with virulent cultivations, was protective. In other cases the serum was not protective, and this was due either to the rabbits not being perfectly immune, or to the fact that the serum was removed at the wrong date. The experiments of Klemperer with the serum of patients recovering from the effects of pneumonia were described. He made but a few experiments, and was only able to prolong the life of the inoculated rabbits. The serum removed by a blister from patients in the acute stage, injected either simultaneously with or previously to inoculation, exerted a bad effect, and caused death earlier than in the control experiment.

Dr. A. E. Wright then read a paper on the "Bacteriology and Pathological Chemistry of Pneumonia," in which he stated that the crisis which ends an attack of pneumonia is very similar to that in connection with spirillum fever, and this spirillum fever is a typical septicæmic infection; so that if we could succeed in understanding what occurred in the organism in the crisis of spirillum fever, it would help us to understand what occurs in the crisis of what we may now provisionally term "pneumococcal fever." We learn the following facts from Vandyke Carter. When spirillum fever is at its height we have an enormous proliferation of white corpuscles in the blood. We have also a number of free spirilla in the blood at the same period. When the crisis supervenes the white blood-corpuscles diminish rapidly, and *pari passu* with their diminution the spirilla disappear from the blood. These changes are in nearly all cases associated with an excessive turgidity, tumefaction, and tenderness of the spleen or the liver. Now, this triple phenomenon of a diminution of the white corpuscles, a disappearance of the bacteria from the blood, and the tumefaction of the internal organs, especially the spleen and liver, can be experimentally produced. We need only, as Werigo has shown, inject bacteria or particulate matter of any kind, such as carmine grains, into the blood, and we shall immediately produce our triple phenomenon. Almost all the polynuclear white corpuscles disappear from the blood in the next few minutes, and on killing the animal we find the bacteria or particles in the internal organs, chiefly in the spleen and liver, and with them the polynuclear corpuscles. We further find many of the bacteria are lodged in the interior of these polynuclear white corpuscles; we thus see that the disappearance of white corpuscles from the circulating blood, the disappearance of the bacteria, and the tumefaction of the internal organs, are all signs of a phagocytic reaction, which eliminates these elements from the circulating blood. To apply these facts to the pneumonic crisis during the fever's height, there is an enormous increase of blood-corpuscles, especially of the polynuclear white. When the crisis occurs we have a very rapid fall in their number. If our hypothesis is true this lessening should go hand in hand with the critical fall of temperature associated with a process of phagocytosis and with an elimination of pneumococci from the blood. Passing on to the pathological chemistry of pneumonia—suppose that the pneumonic fever has ended with a crisis, and that it is over, and the inflammatory process has come to an end. Our patient is, however, not well yet, and it is not merely the question of recovering the lost strength. He has not simply to convalesce, but to undo all that the local inflammatory process has done. He has to reabsorb into his system, and then to excrete, substances which are contained in the enormous mass of white corpuscles which is filling up the alveoli of the lungs. Almost the entire substance of the white blood-corpuscle consists of a nucleo-albumin, and this nucleo-albumin is identical with the nucleo-albumin originally prepared by Woolridge from the white blood-corpuscles of the thymus gland, the injection of which was

shown by him to be followed by intra-vascular thrombosis; pneumonic lung extract in solution is comparable to blood plasma, and injected into the blood of a dog, kills the animal at once with intra-vascular thrombosis. On the other hand, it is possible that the absorption of the nucleo-albumin from the lungs may take place so gradually that its absorption may present no analogy with such injection. We should then have no fear in the direction of intra-vascular thrombosis. We should have to deal with the results of a slow injection of nucleo-albumin into the blood, viz., a lessening of blood coagulability analogous to the diminution produced in animals from an injection of peptone, and might be followed in man, as it is in a dog injected with peptone, with diarrhœa. Perhaps many of the critical diarrhœas may be explained in this manner.

Dr. Washbourn, in reply to a question, said that neither antitoxic nor curative power appeared to reside in the serum of animals affected with pneumonia, and there were no late developments comparable to the paralytic seizures in diphtheria.

IS ANTITOXIN OF ANY VALUE?

To the Editor of the Medical Record.

Sir: Your issue of December 29, 1894, contains an editorial headed "An Attack on the Diphtheria Antitoxin."

The article is seemingly a *résumé* of Dr. Hansemann's paper, read before the Berlin Medical Society, and the views of the editor of the Medical Record; both, according to my opinion, being erroneous and of a misleading character.

First, as to Hansemann's conclusions, they might carry weight, he being, as you state, an assistant to Virchow, were it not for the fact that at a subsequent meeting Virchow completely disavowed Hansemann's conclusions. Secondly, so far as the Loeffler bacillus is concerned, every bacteriologist having given diphtheria special study will, without prejudice, admit the presence of the Loeffler bacillus, either alone or accompanied by various other bacilli and micrococci, consequently it is not an astonishing factor that this bacillus should be found in rhinitis fibrosa, or in the healthy throat.

Now as to the three qualities of the antitoxin, viz., its therapeutic action, its harmlessness, and its immunizing power. I base the following statements concerning these three topics upon my observations of Roux's serum, as I saw it prepared at the Pasteur Institute, Paris, and in the service of Dr. Chaillon, in the Hôpital des Enfants Malades. In the first place, Gottstein, whose pamphlet you cite authoritatively, does not include among his statistics those of the above-mentioned important clinic, which, from my last personal observation, December 15, 1894, exhibit a mortality of eight per cent. only, and although every sore throat (angine) was subjected to the serum treatment only those exhibiting the Loeffler bacillus were included in the diphtheria column, including those cases in which the Loeffler bacillus was accompanied by the streptococcus, *i.e.*, the organism causing broncho-pneumonia, and thus aggravating the original disease. In view of these facts are not the above figures sufficiently significant?

As to the serum injections not being harmless, I must again join issue with the editor and with Dr. Hansemann, and as it is a pathological fact that albuminuria is present eight times out of ten, and of great prognostic value, I claim that, so far as its presence in the serum is concerned, it is of no significance except to further demonstrate the therapeutic value of the serum, for most of the cases cited above have shown a decrease of at least fifty per cent. albumin in the first twenty-four hours following its exhibition.

It astonishes me that Dr. Hansemann and the editor of the Medical Record do not attribute the erythema, post-diphtheritic paralysis, and other well-known pathognomonic features to the serum, and I ask these gentlemen in all candor whether the decreased mortality, taken precisely from the source recommended by them, viz., clinical experience, showing a decrease to eight per cent. mortality—and this is placing it high—is not of itself a sufficient defence of serum therapy as applied to diphtheria?

As to its prophylactic value I quote from your issue of the Medical Record, September 22, 1894, p. 375: "Quite lately Dr. Katz has inoculated 72 children who had been exposed to the disease. Of these only 8 were attacked, and they so slightly as to be free from any evil consequences."

In conclusion, let me say that I heartily agree with you, sir, that it would be not only a disappointment to all well-wishers of humanity, but would be a serious blow to the rising prestige of medical science, if, after all, the serum treatment should fall short of its high expectations. This contingency need not be feared, provided that the application of the serum be kept out of the hands of the charlatans, and also that its proper preparation by experts be a *sine qua non*.

A. Gaston Roeth, M.D.

105 Mt. Vernon Street, Boston, Mass.

[In the discussion of subjects claiming the attention of the profession the Record is never antagonistic for the sake of appearing so, but always cautious in its interpretation of facts. It takes no stand for or against antitoxin, but is still open to conviction. We are merely waiting for more facts. In the meantime in this case, as in others, both sides have a fair showing.—Ed.]

THE FREE LAW LIBRARY AND MEDICAL MEN.

To the Editor of the Medical Record.

Sir: While I agree with "Old Subscriber" (p. 284), that the free dispensaries are much abused, I would like to have his attention called to an error about our legal fraternity into which he has fallen. He says, that a friend, not being a member of the library, "was not allowed to look into a book at any of the law libraries of this city." There is a law library in this city which is open to all who wish to consult the volumes upon its shelves, except to resident lawyers who are non-members of the association maintaining the same, and even they are not actually excluded. This library is in the Post Office building, and is provided with chairs, tables, stationery, and attendants to get the books, the use of all of which may be had for absolutely nothing.

Yours truly,

Francis B. Hays.

72 William Street, New York, March 2, 1895.

HOW MEDICAL CHARITY IS ABUSED.

To the Editor of the Medical Record.

Sir: If "Old Subscriber" of last week is as old as he pretends he must know that what he has to say has been said a hundred times in the Medical Record, *id est*, if he reads as well as he writes, and he must also know that talking has done no good. The remedy—and the only one I know of—lies in his own hands. The next time, and whenever he has need of a consultation or has a patient to send to a specialist, let him avoid the man who daily robs him by indiscriminate dispensary work and pick out instead one who regards the rights of his fellows. There are men at the heads of dispensary classes throughout the city enjoying large special practices who boast that they have no care for the financial standing of their dispensary cases so long as they furnish the required material for clinical purposes; and so far as the complaining doctors go, they say, "let them go and be blanked." So long as they can do this and keep

the support of the general practitioner they will hold the same views. The moment they find it affecting their pockets they may at least cease to pride themselves upon their dirty treatment of their professional brethren. Let the non-dispensary men look to their rights and they will soon have less wrongs.

New Instruments.

AN IMPROVED URETHRAL IRRIGATOR.

BY C. WAECHTER, M.D.,

NEW YORK.

IN subacute and chronic inflammation of the posterior urethra, irrigations are of good service. The instruments on the market for this object seem to me to be more or less deficient; hence I requested Messrs. Lincoln & Luchesi to manufacture one which is seen in the accompanying cut. The instrument has superficial

grooves, the flow of the stream is directed backward, the bulb being somewhat larger than the tube; it is made in two sizes. I have been using this irrigator for several months with good results. It is advisable to begin with weak solutions, gradually increasing the strength. The substances which I use are: boraci and tannic acid, permanganate of potassium, nitrate of silver, etc.

220 EAST TENTH STREET.

"ISCHATIC CRUTCH."

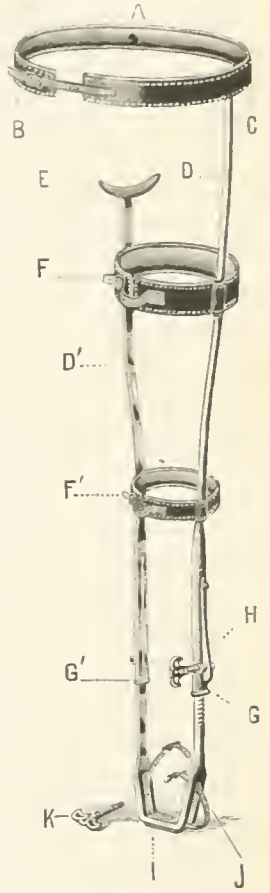
BY H. HODGEN, M.D.,

ST. LOUIS.

IN the treatment of a case of hip-joint disease, some time ago, an abscess formed which burrowed under the perineal straps. The patient was put to bed, the abscess aspirated and injected with iodoform and glycerine mixture; this was repeated once or twice, and the abscess cavity seemed to have closed. The Sayre long hip-splint, which had been used in this case, was applied. After a week or ten days the cavity again refilled, probably from the irritation of the perineal band; the patient was again put to bed, cavity emptied and injected with iodoform and glycerine, and, as before, was doing well, but upon the reapplication of the "Sayre hip-splint" the cavity again became inflamed. It was then decided that an apparatus which would make extension and yet allow the patient to walk would be necessary.

The condition of this patient not being the best, it was considered essential that he have as much freedom as possible, to derive the full benefit from exercise, fresh air, and sunlight. It occurred to me to use "Judson's Ischatic Crutch," but here again the perineal band would have pressed upon the cavity. I next thought of using the ring form of knee-splint, which is used quite extensively in New York. Upon trial, however, it was found that the padded ring in the perineum pressed upon the cavity, as had the perineal band. It was then decided that some apparatus having a short bearing surface which could be fitted to the ischium would be necessary.

In the apparatus that I have gotten up, it will be seen that the pelvic steel band A is much longer than on the ordinary hip-splint, surrounding about nine-tenths of the pelvis. This is made long, so that a firmer hold for the upper end of the splint can be taken on the pelvis. The buckle B is placed about the centre in front, in this way giving much greater stability, so far as lateral motion is concerned, and enabling one to overcome eversion and inversion. The long external upright D is riveted tight at an angle to the pelvic band at C. This upright extends down nearly to the ankle. The inner upright D′ extends from the tuberosity of the ischium down to a point corresponding with the upright D. To the upper end of D′ is fastened loosely, with plenty of lateral motion, the crutch E; this is made of quarter-inch brass rod of sufficient length to catch a good hold on the ischium. It is bent upward and outward in front, and extends nearly straight behind; the length of this, of course, depends upon the size of the patient. The anterior part should ordinarily be about one-third shorter than the posterior. The steel bands F and F′ are riveted lightly to D and D′, and surround respectively the thigh and leg, so as to prevent any movement of the leg in the splint. The movable portion I works into D and D′ at G and G′, thus allowing for the extension of the splint and for the extension of one side beyond the other. The strap J is the ordinary strap of the Sayre splint; the catch H on both D and D′ is automatic in its action. Upon pressing the key K into the opening, the catch is lifted and extension can be made; upon the withdrawal of the key, the catch immediately springs back into position at the notch corresponding to the opening. This I consider a very great improvement over the old-fashioned catch with a ring to hold it. This is the invention of A. S. Aloe Co., of St. Louis, who now put it on all their apparatus where extension is needed.



The weight of this splint is somewhat less than that of the Sayre long hip-splint; as the weight of the body is borne by the upright D′ there is no lateral strain.

In taking measurement for this brace, the steel portion of the pelvic band should extend, as above stated, about nine-tenths of the distance around the pelvis. The external upright should extend from the crest of ilium just above the great trochanter, to the same distance as the Sayre splint. The inner upright should be measured from the tuberosity of the ischium to a point corresponding with the lower end of the outer.

To ascertain the relative position of the crutch and of the riveted upright at C, measurement should be taken from a point just above the greater trochanter on the crest of ilium around the front of the thigh to tuberosity of ischium. The second measurement should extend from the first point around behind to the tuberosity; as will be seen, this will throw the crutch back of the outer upright above.

This splint gives almost complete fixation, and you are able, of course, to get any amount of extension which a patient will bear. If it is deemed necessary that complete, or nearly complete, fixation should be used, a cap of hard rubber moulded to the tuberosity of the ischium can be affixed instead of the crutch-head; all of the weight then will come upon the tuberosity of the ischium, and taking the three points, C, E, and J, it is possible to almost absolutely fix the joint.

In cases in which the limb is adducted, it is only necessary to make the upright D a little longer than D', thus tending to throw the leg out. In cases of abduction, if D' is made slightly longer than D, the tendency will be to overcome this deformity. There is no claim for the involvement of any new principle in this splint, it is simply a new application of an old principle; nor do we claim that every case of hip-joint disease should be treated with this splint, nor that a given case should be treated in all of its stages with it. I have it in use now upon three or four cases, and the patients have worn it with more comfort than the ordinary hip-splint with the perineal bands. A disadvantage of the old hip-splints has been in keeping them adjusted on cases that you cannot see at any time you choose. The perineal bands stretch and the attendant places the tongue of the buckle in the same holes in which you placed them, thus relieving the extension. In this crutch that disadvantage has been done away with. In the old splints the weight of the body when the patient steps comes on the pelvic band; this is apt to sag, letting the diseased side down lower than the well side, thus producing adduction. In the old splint we can overcome the adduction with little or no trouble by the abduction screw, but in cases of abduction the only control which we have over the deformity is through the length of the perineal band, thus tending to overcome it. In this splint the entire weight rests at once upon the inner upright D'.

The only change that can take place in the adjustment of the splint is through the strap J; this, of course, will become stretched some, on account of the weight of splint coming on it at each step, but it will not stretch nearly so much as the perineal bands, which support at each step the entire weight of the body. The stretching of the strap J, of course, will be the same in this as in the old splint.

There are a great many patients whose general condition is such that it is not advisable to keep them in bed or confine them any more than possible. Of course, in the acute stages of an acute ostitis of the hip, it is necessary that the patient be confined, and also during the exacerbations which come on from time to time; but after the acute process and at times between the exacerbations, it is necessary for a patient to be allowed as much freedom as possible. This crutch gives them a firm support, as much extension as they require, and as much or more fixation than the ordinary hip-splint. It does not give the fixation that the Thomas splint does, but it is simple and effective in its action, and there are not so many parts to give way and be repaired.

The cost of the splint is only three dollars more than the ordinary Sayre splint.

A NEW UTERINE DILATOR AND IRRIGATOR.

By H. B. ADLER, M.D.,

NEW YORK.

Having frequent occasion to treat puerperal patients, where either placental tissue was adherent or loosely retained in the uterus, where curetting and irrigation was necessary, I have always met with the greatest difficulties in obtaining an instrument which should have the combined virtue of sufficiently dilating the os uteri and giving a return flow strong enough to carry off the débris. I have used different instruments for the purpose and always found them inefficient. We have one in use now which dilates sufficiently, but the operator is compelled to apply with his hand a constant graduated force upon the instrument, which is next to a physical impossibility, and in order to introduce the instrument into the os, the operator is compelled to keep his hand between the handles, so that the dilating part of the instrument may not dilate prematurely. Aside from all this the instruments when in use cannot be kept aseptic, by reason of their peculiar construction. I therefore have been led to devise an instrument for dilating and irrigating the uterus, as well as a suitable curette combined, which can be kept thoroughly aseptic. It is composed of two parts. Its *modus operandi* is that of the ordinary uterine dilator; the injector is almost a straight tube with a calibre of about a quarter of an inch, sufficiently large to admit a large rod for cleansing purposes. The instrument is held in position by an adjustable spring, and locked by a patent lock of the latest design and simplicity. The instrument, by reason of its aseptic capabilities and the simplicity of its construction, will at once commend itself to every gynecologist and obstetrician.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 2, 1895.

	Cases.	Deaths.
Tuberculosis	108	133
Typhoid fever	4	3
Scarlet fever	123	29
Cerebro-spinal meningitis	3	2
Measles	120	15
Diphtheria	224	35
Small-pox	0	1

A Plea for Conculcation.—Sir Benjamin Richardson asks the medical profession to accept the word "conculcation" as a kind of philosophico-medical antithesis to "inoculation." Perhaps Sir Benjamin has as good a right to coin a new, or half new, word as most of the medical writers who have added barbarisms to the dialect of medical science. Conculcation, to use Sir Benjamin's own definition, consists in "the one grand element of perfect cleanliness in every nation, every family, every individual." That is the old and tried method of sanitary progress; and that, much more than inoculation, is the god of this venerable sanitarian's idolatry. He speaks, indeed, of inoculation with small respect. Is it worthy of being called a method of sanitation or disease prevention at all? he asks. It "pretends to render the body immune against diseases," he says; and it "predicts the greatest triumphs for its future." But at best it only professes to "prevent one disease by producing another." It appears to Sir Benjamin to be a method by which, whatever else happens, "disease" in some of its forms must be "eternally perpetuated."

A Cheap and Efficient Disinfectant for the Sick-room.—The fetid exhalations emitted by the fæces are a source of great annoyance to patients condemned to a prolonged sojourn in one room, as is the case in, for example, typhoid fever. M. Meillère strongly recommends the following powder as an efficient and very cheap deodorizing and disinfecting agent: Sulphate of

zinc, 1,000 grammes; sulphuric acid, 5 to 10 c.c.; essence of mirbane, 2 c.c.; coloring matter (*e.g.*, indigo blue), 15 centigrammes. About five grammes of this salt are placed in the bedpan before it is used. Contact with urine or liquid stools determines prompt solution of the salt, deodorization is instantaneous, and the liquid excreta are at once sterilized. The fetor is transformed into a rather agreeable odor. The employment of this method allows also of the preservation of the excreta for microscopical examination.

Up to Date.—"No!" exclaimed the fox, loftily. "I don't care for the grapes at all. Appendicitis? Not on your life!"—*Detroit Tribune.*

Typhoid Fever and Sewer Gas.—Typhoid fever cannot be transmitted by sewer gas, is the report of the experts to the London Common Council. It is also claimed that the bacilli of the disease, also, find it hard to live in town sewage.

Against the "Christian Scientists."—Following is the full text of the measure now before the New Hampshire Legislature to govern and regulate fraudulent medical practice and the so-called Christian science or faith cures:

SECTION 1.—No person within the limits of this State shall treat, attempt to heal or cure any other person or persons by the so-called Christian science or faith cures.

SEC. 2.—If any person shall treat, attempt to heal or cure, or claim or pretend to heal or cure any other person or persons by either of said methods, and shall directly or indirectly accept or receive any money or other thing in payment for or on account of such services, or directly or indirectly accept or receive any gift or reward therefor in any form, such person so offending against the provisions of this act by so accepting or receiving such money, gift, reward, or other thing, shall be fined a sum not exceeding three hundred dollars ($300) for each and every offence, and half of such amount to be given to the complainant, the other half to the State.

SEC. 3.—This act shall take effect upon its passage.

Stamping out Tuberculosis.—It is estimated that it will require $500,000 to stamp out tuberculosis among the cattle in the State of Massachusetts. The following are the figures submitted at a meeting of the Committee on Public Health and Agriculture of the Massachusetts Legislature recently: Whole number of cows in the State, 186,806; neat cattle other than cows, 47,528; number under one year old, 15,000; total number, 249,334. Ten per cent. of these being the number estimated to be infected, 24,933. Average value of these at $20 apiece, $498,660. Cost of making the test and sundry expenses, $101,340, making a total of $600,000, to which should be added $50,000, for salaries for the commissioners for five years, making a grand total of $650,000. A bill before the Michigan Legislature provides that all persons, before they can teach public or private schools in Michigan, shall be examined and obtain a certificate from a physician that he or she is not afflicted with any communicable form of consumption. In support of the bill it is asserted that teachers having the disease have communicated it to their pupils simply by coughing and expectorating on the floor. Another bill before the same body calls for an appropriation to buy ground in the vicinity of the city of Ann Arbor, whereon to build and equip a consumption hospital.—*Journal of the American Medical Association.*

The Question of Contagion in Tuberculosis.—Dr. Addison S. Thayer, of Portland, Me., in a recent discussion before the Maine Academy of Medicine, remarked as follows: "There were three young men belonging to three different families in the villages of North Gorham and North Windham, who were members of the local band there, brass band. These three fellows used in common a second-hand brass instrument, hired from a music-dealer in Portland, and were the only members of the band who did use it. Now we all know that blowers on brass instruments deposit in the interior of the convolutions of the horn a good deal of their spittle, for which they have an outlet in the bottom of the horn and which they get rid of also by tipping the horn upside down. So that it seems to me we could not have, if we tried to invent one, a better trap for catching tubercle bacilli and for distributing them to the next user of the horn than this instrument furnishes. Now practically the result of the use of that second-hand horn by the three men is this: By the advice of Dr. Harper two of them have gone to Colorado and one to Southern Pines to be cured, if possible, of tuberculosis. This circumstance in itself would not furnish an argument against Dr. Wedgwood's position except for an additional series of facts. Dr. Dunn, who practised for seventeen years in Windham, was thoroughly acquainted with two of these families, and Dr. Harper has investigated the third. He says it was sound stock clear through. Dr. Dunn says there has been no consumption in either of the two families that he knew; they were healthy, rugged, New England farmers.

"I think we all believe in heredity; but investigators who have experimented to find out whether tubercle bacilli can be actually transmitted tell us there are some cases where they are transmitted by the mother to the fœtus, while the consensus of opinion is that the father cannot transmit tubercle bacilli to the child except by way of the mother. The appearance of tuberculosis is another standard for us to go by. In young children tuberculosis appears oftenest in the glands, in the cervical glands, bronchial glands, mesenteric glands, and so on; it is a milder form of the disease than tuberculosis of the lungs which we see in older people. In other words, the child is born with a peculiar weakness, proneness, vulnerability, which is undoubtedly hereditary. An invasion of tubercle bacilli from outside may develop this proneness into glandular tuberculosis during childhood, or into pulmonary tuberculosis later on.

"Now for the practical side of this. Suppose we believe in the hereditary theory as thoroughly as our fathers did, what are we going to do about it? We can do no more than if we believed the opposite theory. In either case we can place a child under the very best surroundings, give him every chance to repel the invasion, make the soil as unfertile as possible; but, believing as we do now, we can besides do a good deal to prevent the disease. We can do it by disseminating just such knowledge as we are talking over to each other here to-night. I think there is great advantage in having this subject brought up in a society like this which includes not only doctors but laymen, which includes people who would remember an incident like this of the three healthy young men who became infected by using a brass instrument. If people only knew these things we are sure that the progress of tuberculosis would be very effectually stayed, all the sputum, as Dr. Dana says, would be disinfected, and the number of victims would be enormously diminished.

"Now as to treatment after the disease is established. It seems to me we can do good by propagating the gospel of fresh air. We have had it already said to-night that medicines accomplish very little. To be sure creosote, guaiacol, and all these things are efficient to some extent, but if the disease is well seated we all know how powerless we are to throw it off. And yet laymen as well as physicians have seen people who say, 'Why, twenty years ago I was given up, by all the doctors who examined me, to die of consumption; I threw away all medicine; I lived out-of-doors, I rode horseback, went ranching in the West,' or something of that kind, 'and here I am to-day, a healthy man.' We know that rabbits and monkeys confined in cages are susceptible to tuberculosis, whereas rabbits and monkeys allowed to

run free in their natural way never get it. After the disease is established, the lesson we ought to impress is the value of fresh air."

The Treatment of Bleeding from the Nose.—Dr. Baumgarten, of Budapest, recommends the following methods in the treatment of epistaxis: A thorough examination of the inside of the nose must be made in order to discover where the bleeding comes from. Usually there are to be seen at the anterior part of the septum, rarely elsewhere, one or more small superficial vessels of a red color, or else little nodules, erosions, and varicose veins, or a small empty vessel looking blackish on a red background. Occasionally the hemorrhagic spot is covered with fresh blood-crusts which must be softened and carefully raised in order to expose the appearances referred to. If there is nothing of a suspicious nature to be seen, the patient must be made to blow his nose several times. Another method is to apply a tampon of wet cotton to the septum, and press it more and more firmly against the place until the morbid spot bleeds. Sometimes this brings on at once a more abundant hemorrhage, which makes the continued application of the tampon necessary before the bleeding spot can be destroyed. For this destruction the author has used the galvanic cautery or chromic acid, sometimes both. He touches the spot with the cautery, which is very painful, and the wire-loop cannot always be withdrawn while it is still red, so that the eschar is apt to be removed at the same time. Then the small wound bleeds feebly, and it should be cauterized with chromic acid, which, according to Dr. Bresgen, is an excellent hæmostatic. When operating on children or on timid persons Dr. Baumgarten uses the chromic acid only, but the cauterizations must be repeated two or more times after the eschar has fallen or after a fresh hemorrhage. This treatment must be continued until a plainly visible cicatrix is produced. The patient must be told not to scratch the eschar, to apply a little oil or grease to the spot, to keep quiet, to avoid handling his nose, and not to blow it too hard. Sometimes sneezing occurs, and this may bring on a hemorrhage through the eschar. In this case the application must be renewed. A hemorrhage must always be arrested before cauterizing the spot from which it proceeds. After the source of the hemorrhage has been ascertained the spot is washed with warm water, the nostril is dilated, and as large a tampon as possible is inserted, against which the wing of the nostril is pressed with the finger. That generally suffices, as nearly all forms of epistaxis have their origin in the forepart of the nasal passages, but the patient must hold himself erect and remain quiet. After this pressure has been continued for a moment the tampon is slowly withdrawn in order to find the origin of the hemorrhage. A second tampon is then pressed against the spot. The epistaxis is thus often arrested. Afterward the place may be cauterized with chromic acid. The author has often succeeded in covering the bloody points with a layer of chromic acid by pushing the tampon forward very gently; it cannot always be removed immediately, because the wound will bleed anew, and it must be left until the following day or longer if necessary. The author, however, has never had to repeat this for more than three days. He always uses cotton saturated with carbolic acid or some other aseptic cotton, but never iron perchloride, as that only cauterizes. If the blood runs through the tampon or into the pharynx, the physician should use the same means as those employed in the more serious hemorrhages. After the part has been washed with warm water, a strip of iodoform gauze as wide as a finger should be pushed as far as the choana; then the entire nasal fossa should be packed with the same material. This may be done easily and without pain; it is better than Belloq's method, and may be accomplished even with a contracted nostril. With regard to Belloq's method, Dr. Baumgarten thinks it is not sufficient and that it may produce accidents to the ear, etc. In one case, that of an old man who was the subject of advanced arteriosclerosis, Belloq's tampon was inserted, and several tampons were added anteriorly. Two physicians had tried to stop the bleeding, but their efforts had been of no avail. The velum of the palate had been cut, and it was ulcerated and œdematous. The author, who was called in, immediately removed everything, and while the bleeding continued he applied strips of iodoform gauze, and two days afterward the hemorrhage was arrested. As a palliative method, or in cases where the anterior tampon is not efficacious, or where the patient is taking care of himself pending the physician's arrival, the author recommends the use of warm water, which is a better hæmostatic than cold water or ice-water, or else lemon-juice. A solution of iron perchloride is an excellent hæmostatic, he says, but it cauterizes the neighboring region and prevents the physician from distinguishing the diseased spot. When the hemorrhage finally stops, and the bleeding-points are found, they must be cauterized. There is no harm in cauterizing somewhat around the bleeding spot; on the contrary, the indications are to burn the entire vicinity. In cases of arteriosclerosis the author has been obliged to cauterize the entire pituitary surface as far as the choana as the iodoformed strips were removed one after another. These cauterizations should be repeated several times, and every suspected place covered anew with chromic acid. These tampons of iodoform gauze are not disagreeable to the patient, and they may be left for two days. Before removing them the nose should be washed with warm water, and the strips of gauze should be drawn away very gently in order to prevent the hemorrhage from breaking out again, and any suspected places immediately cauterized, even at the risk of touching a healthy spot. The patient may take wine and iron, but should avoid coffee, tea, and effervescing drinks. All internal medicines are useless and harmful.—*The New York Medical Journal.*

The Incandescent Gas-burner.—From experiments conducted by *The Lancet* on different methods of illumination with reference to health, this conclusion is reached: "In considering, in conclusion, the systems of artificial lighting that are in vogue at the present time, the incandescent system of electric lighting must, of course, rank first from the point of view of health, since it affords a soft, agreeable light, without giving rise to any vitiation of the air; there is no combustion, and consequently there are no products of combustion, complete or incomplete. From the same point of view we are bound to place next, in the face of the result of our present inquiry, the incandescent gas-light in its improved form. It is even less productive of carbonic acid gas than the average oil-lamp, and consumes not quite one-half less gas than the existing type of burners, giving rise, therefore, to the evolution of half the heat and half the amount of carbonic acid gas, while its illuminating power, expressed in candles, is more than three times as great as the best ordinary gas-burners or the incandescent electric lamp, each of which does not generally exceed sixteen candle-power, unless a very great expense is no object to the consumer. We are far from saying that the incandescent system of gas-lighting has attained to the highest pitch of perfection; still we are well within bounds when we regard it as the system of gas-lighting which utilizes most efficiently and most economically the full powers or duty of coal-gas as an illuminating agent."

Quarantinable Diseases.—According to the Inter-State Quarantine Regulations recently issued by the Treasury Department, the quarantinable diseases are declared to be cholera, yellow fever, small-pox, typhus fever, leprosy, and the plague.

ENTERIC FEVER IN CHILDREN AND INFANTS—A CLINICAL STUDY.[1]

By WILLIAM L. STOWELL, M.D.,

NEW YORK.

My object in studying my notes of cases has been twofold. First, to ascertain whether or not the clinical picture of this fever differs essentially from the same disease in adults. Second, to ascertain, in part from the literature, if this fever attacks infants, and if so, are the lesions characteristic in them.

The following description, by Dr. Flint, will serve for the adult standard: "From a clinical stand-point, typhoid fever may be defined an endemic disease continuing usually from three to four weeks; very rarely ending under two weeks, and sometimes its duration extending to six or seven weeks; distinguished from the other continued fevers by a group of abdominal symptoms to which characteristic intestinal lesions stand in a causative relation; presenting in a majority of cases a peculiar eruption; occurring especially in the autumnal season; communicable in some way from the sick to the well, and its causation generally dependent on a special morbific agent derived from human fecal excrement."

Under various names the disease has occurred in all climates where man lives or has lived since historic times. For many years it was described among children as "infantile remittent" fever. In 1847 Dr. Wood suggested "enteric fever" as a short name explanatory of the characteristic lesions, and though not perfect, it is the best yet given.

The thirty-four cases of which I have notes occurred for the most part at my classes at the University Medical College, and in the Demilt Dispensary district. As they cover nearly ten years, the small number tends to show that enteric fever is not very prevalent in New York City, although sporadic cases and groups occur every year. With our reasonably good water-supply and complete sewage system, this is as we should expect. New York's annual mortality from this disease is 2.2 per 10,000 inhabitants; that of Philadelphia, 6.6; and Baltimore, with no sewers, 5. (Osler.) The cases further correspond with Dr. Flint's summary as follows:

Duration.—Shortest record, 10 days; longest, 52 days; mean duration, 23.8 days. The adult mean is 28.1 days. (Osler.) Three cases, *i.e.*, 8.8 per cent., relapsed or were reinfected. Of 452 cases in children reported by Rilliet and Barthez, Henock and Earle, 10.1 per cent. relapsed. Adults relapsed, 7.8 per cent. of cases given by Osler.

Abdominal Symptoms.—Tympanites was nearly always present to a slight degree, and also gurgling at the ileo-cæcal valve, as in other diseases of this part. Tympanites was so marked in the boy with persistent high temperature, that his life was despaired of. Diarrhœa was marked in 29.5 per cent. of cases. A few were as markedly constipated, though loose stools usually occurred a few times before recovery. The stools of some answered to the "pea-soup" description. One mother spoke of them as "like a mustard plaster." Hemorrhage of the bowel is not recorded. Diarrhœa occurred in 33.2 per cent. of Osler's 229 adults.

Eruption.—Twenty cases, *i.e.*, sixty-six per cent., are mentioned as presenting rose spots, but I believe more did so, as the rose spots constitute one of my diagnostic points. They usually occurred on the eighth day, though one child showed them on the sixth, and another not until the twelfth day. Twice spots were profuse, and covered the extremities.

Season.—The last four months of the year furnished 73.3 per cent. of the cases, thus warranting the old name of autumnal fever. We know that water purifies itself more rapidly in summer than in winter, and the report of Dr. Edson on Croton water supports the belief. He found by weekly analysis that the number of colonies of bacteria increased steadily through the last half of the year and into January. Prudden has shown that freezing does not kill the typhoid germ, hence its activity does not cease with frost, as does yellow fever. Thus is explained the occurrence of the fever in autumn and winter.

Communicability.—The endemic nature is illustrated by twenty cases, occurring in six groups, and by the two youngest, where the mother was ill in one instance, and both parents in the other. In these I traced cases to a previous one, but did not find the real medium of contagion.

"The special morbific agent" is the bacillus described by Eberth (1880) as a slender rod three times as long as broad, and one-third the diameter of a red blood-corpuscle. These are found in the liver, spleen, kidneys, and blood, as well as in the intestines.

The bacillus of Eberth is generally regarded as having its origin in the dejecta of another case of enteric fever, though a few students think it may, under suitable conditions, develop from the bacillus coli communis.

Age.—The two youngest were twelve months and seventeen months of age, respectively. The mean age 7.97 years.

Sex.—Fifty-nine per cent. were males; forty-one per cent. were females.

The ptomaines produced by the bacilli cause toxic effects, or symptoms, such as fever, delirium, muscular degeneration with its consequent dicrotic pulse, etc. Symptoms occurred as follows: Three cases began with chills. Two of these and another had chills at the end of the illness, as if to shake off the disease. One of these had a chill January 12th and 29th, and February 11th and 16th; he therefore had a typho-malarial fever.

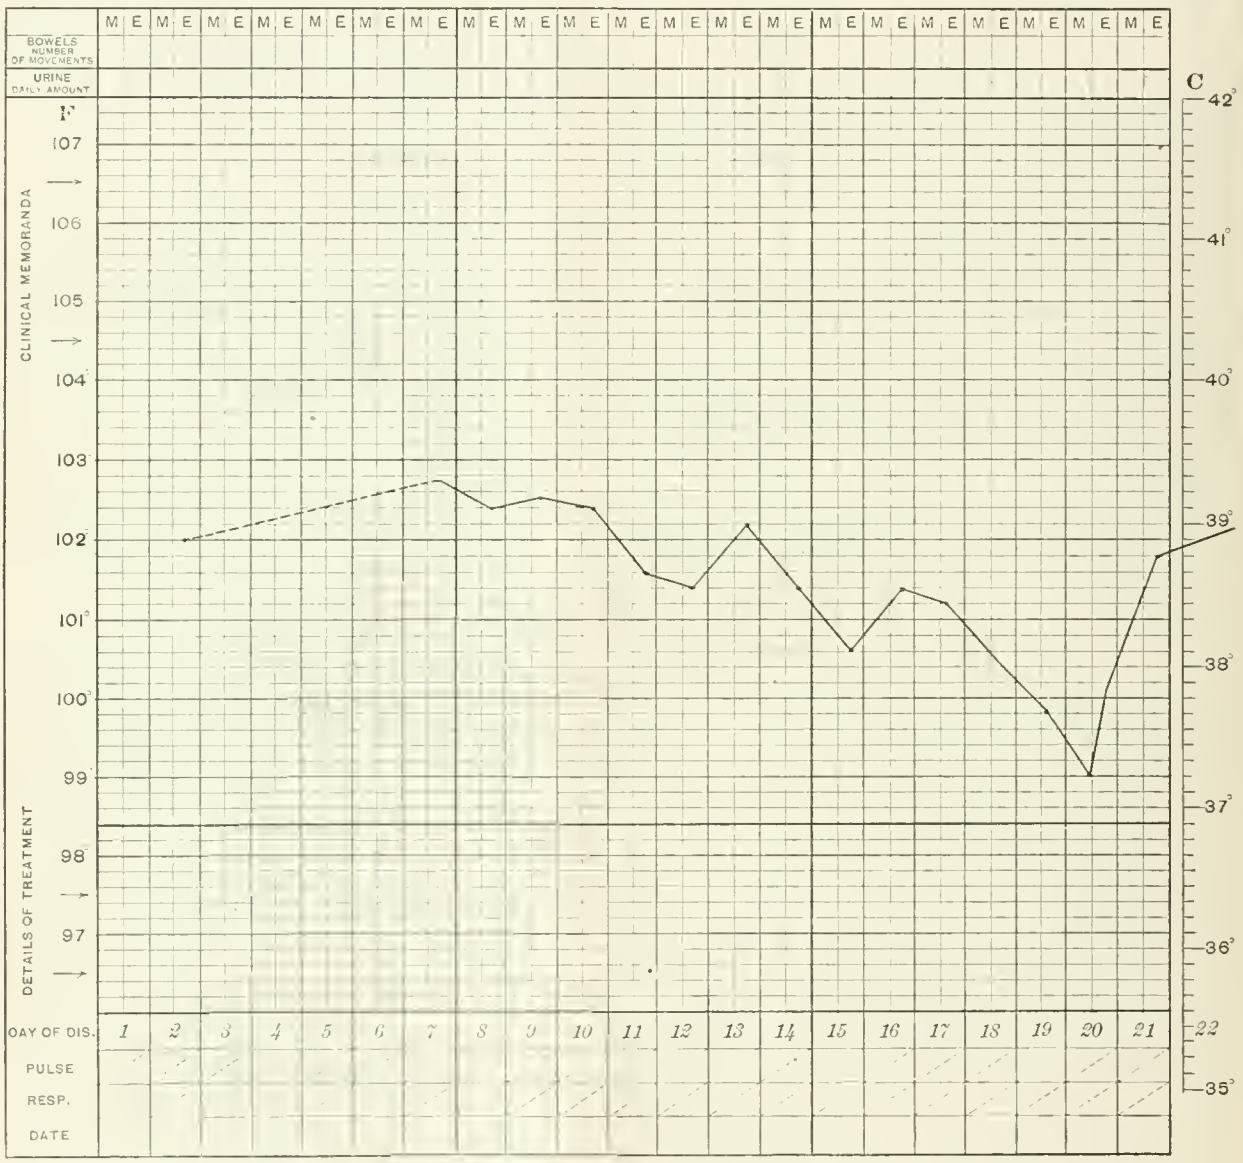
Epistaxis occurred to seven patients, *i.e.*, 20.5 per cent. of cases. One boy went into collapse after a bad midnight attack of nose-bleed. It was hemorrhage from the nose, instead of from the bowel, which nearly caused his death. Presumably it was due to nasal ulceration analogous to the more common intestinal ulceration. The tongue was found moist and coated except in those who had high temperature, or late in the illness, when secretions were often nearly suspended. In a few such the classical "beefy tongue" was shown. Sordes came a few times. Temperature ran high continuously in one case. In others it was irregular, being as high in the morning as in the evening. In a girl who relapsed, the temperature fell the first time by crisis, and after the

[1] Read before the Pediatric Section of the New York Academy of Medicine, December 13, 1894.

second series by lysis. Instead of type charts I have made a composite record of temperature. It does not show so high a range as typical cases are supposed to have. Headache was present as a rule. Mild delirium with senseless talking characterized a few cases, and coma vigil was present in the more severe ones. In two instances delirium was violent. A boy of eight years kept up piercing screams at night. As hypnotics had no effect, and as his skin was dry and covered by sudamina, I gave pilocarpin to induce perspiration. This may seem an odd remedy for enteric fever, but the screaming ceased when sweating began. Henoch mentions a similar case in which it was necessary to give chloroform several times. Great stupor characterized two cases.

fever after the fourteenth day is due to absorption through ulcers. Perhaps this temperature may be so explained, as there was no apparent complication to cause it. This is the boy who had varicella and boils.

K. D——, a girl eight years of age, was sleeping with her brother, aged nine years, when both were drenched by rain through a leaky ceiling. The family at first attributed the illness to this, though both were typical typhoids. The girl had eruption on the extremities, delirium, relapse, complete alopecia, etc. These children had been constant attendants on Case XVIII., which occurred thirty-two days before. This throws a little light on contagion and incubation. Where I was able to trace them, the second case usually followed twenty-eight or thirty days after the first case.



Complications.—Pneumonia happened in three cases, *i.e.*, ten per cent., but was not severe enough to especially modify the history. Varicella and boils or skin abscesses bade fair to exhaust one boy. Peritonitis and pericarditis each occurred once.

A few cases were of peculiar interest. A boy of nine began with vertigo and a temperature of 105° F. This fell gradually to 100.5° F. on the eighth day, when spots appeared. Four days later it reached 105° F., and remained between this and 104.5° F. for fourteen days, when it fell in thirty-six hours to normal. This happened without apparent cause on the thirtieth day of illness. The same evening the temperature returned to 103.5° F. and then declined by lysis. Garlock[1] says

[1] Transactions of the New York Medical Association, 1891.

Ashby and Wright say "no disease is more certain to spread in the houses of the poor than enteric fever," yet with our crowded tenements, containing ten or twenty families, it does not often become endemic. Bronchitis was common, but seemed to remain long in the congestive stage, free expectoration being rare. I did not observe enlarged spleen very constantly, though Earle found it in seventy per cent. of children. Alopecia occurred during convalescence as in adults.

My quartette of characteristic symptoms would be peculiar apathetic, unconcerned expression, fever rising gradually, rose spots, and perverted bowel action, usually diarrhœa. Any symptom may be absent without discrediting the diagnosis. We usually recognize the disease at once, as we would a photograph of an

old friend, without analyzing the features. Liebemeister says, "there is not a single symptom of typhoid fever which can be characterized as pathognomonic."

Differential Diagnosis.—Tubercular meningitis had to be differentiated sometimes. The irregular breathing and pulse, unsymmetrical or abnormal pupils, stupor rather than delirium, and convulsive movements, all differ from enteric fever. A few days of rising temperature and spots will make the diagnosis positive. Bronchitis and cough with few râles is suspicious with increasing fever. Pneumonia usually develops more rapidly than typhoid. Dulness on percussion of the lungs and the crepitant râle decide the case.

Simple diarrhœa and enteritis are not accompanied by fever. Unwise feeding will explain one case, while in this fever the diarrhœa comes on after ten days' illness with almost no eating. Enteritis is characterized by green stools and pain. Diarrhœa in enteric fever is painless. Other eruptive diseases are not liable to be mistaken. The bright-red spots are not larger than a pin's head. They are too small and too few to be confounded with measles or typhus. In variola, typhus, and measles, the eruptions all appear by the third or fourth day, instead of the eighth as in enteric fever. A microscopic examination of the blood would show plasmodii, if the case were malarial.

Treatment is Simple.—Enjoin quiet and fluid diet. Milk is the staple, but I allow all kinds of broths or strained soups. Lemonade and ice-cream are always agreeable to the very feverish.

Remedies.—Cold sponging with or without alcohol. I have not used "tubbing." Medicines are to be given symptomatically. Acetanalide or phenacetine only in extreme pyrexia. Dover's powder for restlessness and delirium. Turpentine or salol are my routine drugs for intestinal antisepsis. Camphor or strychnia when the heart seemed to need them. The less medicine the better.

Mortality.—A girl of twelve years died in stupor at the end of the fourth week. Though not under my care for the last few days, the result would probably have been the same. This death makes the mortality 2.95 per cent.

Although enteric fever in childhood is lightly spoken of, there are many autopsies reported. Henoch found intestinal ulcers in a girl aged three, who died in the third week of illness. He also records perforation during the fifth week in a boy aged eleven. Of 302 patients 21 died, *i.e.*, six per cent. In 11 of these Henoch found ulcers of Peyer's patches. Morrill reports 25 cases with twenty-five per cent. of deaths. One, a boy ten years of age, died of perforation. Reynolds, of Boston, reports a boy aged nine and a half, who died on the thirty-fourth day of perforation and peritonitis. Both books and journals abound in cases like the above.

While ulceration of Peyer's plaeques is characteristic, it must not be forgotten that tubercular ulcers occupy the same site. The latter are irregular in shape and extend around the gut along the blood-vessels. Tubercles and caseous masses lie in the floor and margins of the ulcers. Large spleen does not accompany tubercular ulcers. Follicular enteritis with ulceration is more generally distributed, and with a clinical history will not mislead one.

Whittaker[1] says "one should be slow in childhood to accept the diagnosis of typhoid fever. Most such cases are typhoid conditions of pneumonia, tuberculosis, etc." Meigs and Pepper said (1883) "that the mildness of the disease in childhood may be due to the glands of Peyer being less fully developed than in the adult."

These opinions are somewhat prevalent, but I think the statements erroneous.

Gray[2] says Peyer's patches appear at the sixth month of fœtal life. Minot[3] says "the intestinal glands begin to develop at the third month of fœtal life." Goundobine finds the anatomical distribution of Peyer's patches the same in the infant as in the adult. Kirke[1] states, "it is to be noted that they [*i.e.* Peyer's glands] are largest and most prominent in children and young persons."

Such definite assertions by an anatomist, a physiologist, and an embryologist, added to the many cases found by pathologists, lead us to reverse the general statement of some practitioners. If there be a difference between enteric fever of adults and children, it is not anatomical. Infants are not often exposed to the poison. When they come in direct contact with the germ, they are susceptible enough—*e.g.*, the Montclair epidemic, in which all the infantile cases were traced to infected milk; or the North Boston epidemic, due to infected well water.[2]

Of patients under three years of age I have recorded five, but only two of them in detail. By adding to these nearly all in the literature and records given me by friends, I am able to tabulate eighty-five cases, which should be enough to prove the existence of this disease in earliest life and give some data for comparisons. The youngest occurred at birth or before.

Bednar records a child aged five days, presenting typhoid symptoms and dying on the sixteenth day of illness. A perforation of the intestine was found near the ileo-cæcal valve. Jacobi records a case that died on the sixteenth day of life and sickness, who had large spleen and ulcerated intestine.

Ernst's case is specially noteworthy. The child was born of a mother suffering from enteric fever, and died on the fourth day. The spleen was enlarged, and cultures from it and the blood of the heart showed typhoid bacilli. The babe had a mottled rash on the lower part of the abdomen and lower extremities. This case is complete in etiology, appearance, morbid anatomy, and bacteriology.

Gerhardt goes farther back in reporting an eight-months fœtus born on the seventh day of the mother's fever. This infant had vomiting, roseola, diarrhœa, and large spleen, but recovered in thirty-eight days. Hestelius reports an eight-months fœtus with large spleen and usual intestinal lesions. Eberth has demonstrated typical typhoid bacilli in the organs of four fœtuses aborted by mothers having typhoid fever. Eight fœtuses from mothers not ill with typhoid did not show bacilli.

The report of Oakey is interesting in a negative way. A family of nine persons contracted fever from an infected well. One of them, a woman aged twenty-one, was delivered of a seven-months fœtus which showed no sign of disease. Both mother and infant lived.

Contagion is clearly established in 27 cases, the most interesting group being those of the Montclair epidemic last spring (1894). The 115 cases reported were traced to milk supplied by a dairyman in whose family there were cases of the fever. Eight infants known to have taken this milk developed the fever, and one of them died. The eruption is mentioned in twenty-one per cent. of the cases in the table, while in two it was said to be absent. Diarrhœa seems very common, being marked in nineteen cases, while in two constipation was bad. As only one-quarter of the cases are described in detail, it seems that diarrhœa is more common in infants than in older children, in whom constipation may prevail through the illness. Intestinal hemorrhage occurred in three infants, to one of whom it was fatal.

Mortality in Infants.—Of these 85 cases, 25 died, *i.e.*, 31.76 per cent., a greater mortality than at any other period of life. No doubt many infants have in reality died of enteric fever, though under some other diagnosis. Likewise cases have recovered under other names.

ENTERIC FEVER IN INFANTS UNDER THREE YEARS OF AGE.

Case	Authority.	Sex.	Age.	Origin, etc.	Symptoms, etc.	Result.	Autopsy.
1	Abercrombie, 1817.		6 mos.		Vomiting, diarrhœa.	Died 13th day.	"Patches inflamed, covered by minute ulcers, whitish, ash-colored, honeycombed."
2	Edinburgh Medical Journal, 1820, vol. xvi., p. 329.		7 mos.		Dry tongue, comatose.	Died 9th day.	Bowels healthy, except inflamed spots and ulcers as above.
3	Ibid.		3 yrs.			Died 21st day.	Irregular inflamed patches in ileum, fungus like, mesenteric glands greatly enlarged.
4	Charcellay, 1840 (Gerhardt Kinderkrankheiten).		8 days	Mother well.			Solitary follicles and Peyer's patches swollen and ulcerated.
5	Manzini, 1841, loc. cit.		7 mos.			Died.	Peritonitis with swollen and ulcerated glands bowel.
6	A. Jacobi, MEDICAL RECORD, 1870.		at birth	Lived opposite swampy lots. Mother not typhoid.	Fever, trifling diarrhœa.	Died 16th day.	Large spleen, ulcers of Peyer's patches.
7	Walker, British Medical Journal, vol. i., 1879, p. 347.		15 mos.	Mother ill one week later.	Child had eruption on 4th and 6th days. Erythema is mentioned, a clear case, diarrhœa, etc.	Recovered.	
8	Dr. Wiltshire, loc. cit., p. 427.		6 mos.	Artificially fed. Boy ill next door with same fever.	Well covered by eruption.		
9	Ibid.		6 mos.	Abortion.			
10	Murchinson, Trans. Path. Soc., 1864. (From Med. Chir. Rev., '58, vol. xxii., p. 161.)	Female	6 mos.	Mother ill of same. Youngest in 23 years at London Fever Hospital.			
11	Hennig.		3 mos.	No details.	Had pneumonia also.	Died.	Large spleen, swollen Peyer's patches.
12	Wünderlich.		2 mos.		Rash present.		
13	Freidrich.		6 mos.		Diarrhœa, cough, weak heart.	Died 6th day.	Hyperæmia lungs, spleen large, solitary, mesenteric, and Peyer's glands swollen.
14	Medico-Chir. Review, 1858.		7 mos.			2 died.	Autopsy confirmed the diagnosis.
15	Riliet, loc. cit.		7 mos.				
16	" loc. cit.		10 mos.				
17	" loc. cit.		13 mos.				
18	Editor Medico-Chir. Review.		19 mos.				
19	" " "	Male	2 yrs.				
20	Bednar, loc. cit.	Male	5 days	Mother died of "metritis"?	Vomiting, tympanites, large spleen.	Died 16th day.	Perforation intestine near ileo-cæcal valve.
21	" loc. cit.		11 days		Gangrene left axilla, large spleen.	Died.	Swelling and injection Peyer's patches.
22	" loc. cit.		15 days			Died.	
23	Bartlett, Fevers of United States.		2 yrs.				
24	Taupin, loc. cit.		7 mos.	Had 10 patients under 4 years in 121 cases.			
25	Moore, 1881, Trans. Path. Soc., London.		3 yrs.			Died.	Sloughing of intestines, no perforation. Youngest of 95 autopsies.
26	Robertson, Australian Medical Journal, 1882.		3 yrs.	Seven members of family also ill.	High temperature, diarrhœa, and bowels.	Recovered in 28 days.	
27	Dr. M. P. Jacobi, Arch. Med., 1884.		6 mos.		Spots 10th day, also had pneumonia.	Recovered.	
28	Okey, Peoria Medical Monthly, 1886-87.		2 yrs.	Nine of family ill. Infected clothes washed about a well in use.	A woman of this family, age 21, was prematurely delivered of a 7 months fœtus, which did not show typhoid. Both mother and infant lived.		
29	Farnham, Boston Med. and Surg. Jour., 1888, vol. cxviii.	Female	3 yrs.	Father also ill.	Temperature 104° F. first week, afterward 95.4° to 97° F. Had spots.	Recovered.	
30	Eichorst quotes Hastelin's "Blood Nutrition and Infectious Diseases," Wood & Co., 1886.		8 mos.	Fœtus still-born. Mother aborted while ill of enteric fever.		Died.	Enlarged spleen. Lymphoid enlargement of intestinal follicles and mesenteric glands.
31	Leroux, France Méd., Paris, 1889, vol. I.	Female	11 mos.		Spots.	Recovered in 28 days.	
32	Fuller, London Lancet, 1891.	Female	9 mos.	This and following case ill at same time in house with a woman ill of enteric fever.	Diarrhœa, dry tongue, no spots. Occurred in August. Temperature 102°F. at onset.	Died 13th day.	Spleen not large. Intestine showed enlarged, softened, and breaking-down glands.
33	Fuller, loc. cit.		18 mos.			Recovered.	
34	Dr. Ogle, London Lancet, vol. i., 1892.	Female	4½ mos.	Was fed condensed milk.	Ill Sept. 11th to 17th. Marked rickets. Died on way to hospital.	Died.	Typical intestinal lesions. Spleen large and soft, ragged ulcers in intestines, but no perforation.
35	Henoch in Diseases of Children, Sydenham Soc. Trans., 1889.	Female	3 yrs.			Died 21st day.	Numerous ulcers in intestine, Peyer's patches large, no cicatrices.
36	Ibid.	Male	3 yrs.		Recovered in 10 days, but died 10 days later of croup.		
37	Ibid.	Female	2 yrs. 6 mo.		Ill 7 weeks. Died 7th day of relapse.	Died.	Two ulcers down to muscularis.
38	Ibid.		6 mos.		With all symptoms, including temperature curve.	Recovered.	
39	Ibid.		7 mos.		With all symptoms.	Recovered.	
40	Ibid.	Male	3 yrs.		Temperature on 7th day 104° F. A.M., 106.2° F. P.M. Temperature fell next day to 98.1° F. with no subsequent rise		
41	Dr. England, Canada Medical Record, 1890, vol. xix.		8 mos.	Hand fed.	Large spleen, diarrhœa, spots, tympanites, high fever.	Recov. in 3 w. eks.	
42	H. N. Read, Brooklyn Medical Journal, 1889.		4½ mos.			Died 17th day.	Only death in 22 cases under 10 years of age.
43	Ibid.	Male	2½ yrs.		Highest temperature 105° F.	Recov'd in 30 days.	
44	Ibid.	Male	3 yrs.		" " 106° F.	Recov'd in 28 days.	
45	Ibid.	Female	18 mos.		" " 105.5° F.	Recov'd in 28 days.	
46	Ibid.	Male	3 yrs.		" " 103° F.	Recov'd in 17 days.	
	Keating's Cyclopædia of Diseases of Children.						
47	Rerhem.		14 mos.				
48	Archambault, Gaz. Méd. de Paris, 1880.		21 mos.	Mentions 9 cases between 2 and 4 years of age in total of 164 cases.			
49	Stephens, Keating's Cyclop.		12 mos.	Mentions 28 between 3 and 6 years of age in a total of 63 cases.			
50	Parrott, loc. cit.		3 yrs.		Died of intestinal hemorrhage.	Died.

66	P. Ernst, Sarjou's Annual. 1891.	.....	at birth	Mother had typhoid at the time.	Babe jaundiced, covered by a mottled exanthematous rash on lower extremities and lower part of abdomen.	Died 4th day.	Spleen enlarged. Cultures from spleen and blood of heart gave typhoid bacilli.
67	Ashby, London Pract., 1891, vol. xxvi.	.....	3 yrs.	Two other cases in the family.	(Spots in 78 per cent. of cases.)	Recovered.	
68	Ibid.	.....	3 yrs.	....	....	Died 8th day.	Ulcers of larynx as well as intestine.
	Reported to author. Not published before.						
69	Dr. E. Le Fevre.	.....	22 mos.	Other cases in family.	Hemorrhage on 28th day.	Recovered.	
70	Ibid.	.....	2 yrs. 5 mos.	Ibid.	Had spots.	Recovered.	
71	Dr. Geo. McNaughton, Brooklyn.	Male	2 yrs.	(?)	Temperature 103° F. not exceeded. Constipated, eruption fairly profuse, no hemorrhage.	Recov'd in 3 weeks.	
72	Dr. Rupp.	Female	13 mos.	Not known. Nursed by careful well mother.	Headache from onset, with meningeal symptoms. Temperature rose to 103° F. on 6th day, ranging from that to 105½° F. several days. Eruption 6th to 11th day. diarrhœa, large spleen. Temperature fell gradually, and with it diarrhœa ceased.	Recov'd in 19 days.	
	Cases under 3 years in the Montclair epidemic of 1894. Notes sent me by Dr. R. C. Newton:			Of 115 cases in town, 8 occurred in infants 3 years or under who were fed on the infected milk.			
73	Dr. Newton.	Male	11 mos.	Same family.	Aphthous sore mouth, spots, diarrhœa, and tympanites.	Recov'd in 16 days.	
74	Dr. Newton.	Female	2½ yrs.		No diarrhœa, spots marked, tympanites. Temp. 103° F.	Recov'd in 1 week (?)	
75	Dr. Smith.	Female	3 yrs.	....	Diarrhœa, rash, sudamina. All symptoms.	Recov'd in 14 days.	
76	Dr. Wilson.	. .....	2½ yrs.	... .	Eruption. Mild case.	Recov'd in 14 days.	
77	Dr. Whitehorne.	Male	12 mos.	Fed milk and barley-water.	Erythema at onset. Rose rash 13th day. Highest temperature 105° F.	Died 22d day of convulsions and collapse.	
78	Dr. Shelton.	Male	3 yrs.	Drinking infected milk once or twice.	Mild symptoms.	Recov'd in 4 weeks.	
79	Dr. Brown.	Female	18 mos.	....	Eruption present.	Recov'd in 21 days.	
80	Dr. W. B. Noyes quotes Dr. Brown, and gives notes of same cases as Dr. Newton above. MEDICAL RECORD, vol. xlvi.	Female	3 yrs.	Sister of case above.	Constipated, no rash, tympanites, marked nervous symptoms.	Recov'd in 28 days.	
	Author's cases.						
81	....	Female	9 mos.				
82	....	Male	3 yrs.				
83	... .		2 yrs.	Child 2 years brought to the College, but subsequent history unknown.	Temperature 103° F. Sudamina, etc.		
84	... .	Female	12 mos.	Father and mother ill at same time.	Dry cough, fever, diarrhœa.	Recov'd in 10 days.	
85	....	Female	17 mos.	Mother has enteric fever.	Marked stupor. Temperature 105° F. Well in 3½ weeks, when relapsed.		

The figures given may be considered representative, as the cases occurred in all lands, are from hospital and private practice in city and country, and are both epidemic and endemic.

Conclusions.—1. The disease is common in childhood and not more rare in infancy than is explained by lack of exposure. 2. The types and varieties do not differ materially from those of adults. 3. The duration is shorter because the tendencies in childhood are more toward growth and repair than in the adult, whose nutritive functions are all employed in repair alone. 4. The prognosis is best in children because they usually have healthy organs to fight the invader, and so have few complications. 5. In infants the mortality is

high because the extremes of life are feeble, one having had no latent strength, the other having exhausted it. 6. Those who die of enteric fever itself, die, as adults do, of perforation or exhaustion.

28 West Thirty-sixth Street.

A CONSTRICTION OF THE ILEUM BY OMPHALO-MESENTERIC REMAINS; PARTIAL ENTERECTOMY; RECOVERY.[1]

By HELEN C. PUTNAM, A.B., M.D.,

Providence, R. I.

Owing to the rapidity with which it was necessary to close the surgical operation in this case, several points of interest could not be investigated. Since the question has been raised as to whether there had ever been an appendicitis, it appearing possible to otherwise account for its symptoms, and since the subject is still *sub judice*, as the cæcum and vermiform appendix were not found and examined, the case is reported with considerable fulness.

The following points are of interest:

1. The special difficulty arising from the patient's history of relapsing and recurrent appendicitis in correctly diagnosticating the essential lesion during the first forty-eight hours, and the early obscuring of the essential lesion by the prompt development of symptoms of appendicitis and peritonitis.

2. There being doubt as to the paretic or possible other nature of the obstruction, the policy of waiting so long as general and local symptoms continuously improved, in spite of constant danger of gangrene and of rupture, whereby the risk became less of relighting violent serous inflammation by cœliotomy, and, therefore, better chance was secured for successful primary operation upon the intestine—up to the present date one of the most formidable in surgery, even under antiseptic precautions. In abdominal section for intestinal obstruction, out of 328 cases since 1873, collected by Curtis, there was a mortality of 68.9 per cent. In primary resection of intestine for obstruction, Weir reports a mortality of one hundred per cent. for operation upon the large intestine; Reichel, of seventy-five per cent. for operation upon the small intestine.

3. The pathology and mechanical arrangement of the anatomic lesions found at the operation.

4. The possible questioning, in view of the patient's previous history, as to which was the initial lesion; whether a recurrent appendicitis or peritonitis, remotely caused by exposure or digestive disturbance; or acute obstruction either from angulation of the ileum over the band, or from enteritis localized here, no signs ever being observed of such enteritis or obstruction at this point being caused by fæcal material.

5. The successful issue of an operation for acute intestinal obstruction performed at the end of the ninth day.

The patient was a boy, fourteen years of age, American, of healthy parentage, one of six children, all the others being healthy. As considerable interest in the present illness is derived from his preceding history, a somewhat detailed review of his earlier illnesses is presented. When eighteen months old he had an acute anterior poliomyelitis. Since then he has been the constant object of supervision at home and of treatment either by orthopedists, *masseurs*, or electricians, with a resulting very fair condition of general health and very slight degree of pedal and spinal abnormality. He was not subject to constipation or other intestinal disturbances in infancy and early childhood.

When seven years of age, while in Germany, after two weeks of "a slight cold," he was attacked with "great pain in the right hip and groin," and "soreness to the touch." Notes concerning his illness have been gleaned from letters written home by the member of his family attending him, and from letters given by his physicians. Dr. A. Sebold, of Cassel, diagnosticated appendicitis (*Blinddarmentzundung*, inflammation of the cæcum). On about the third day general peritonitis developed, accompanied by occasional severe colic in the epigastric region. Free evacuation of the bowels several times occurred previous to the sixth day. On this day temperature is noted as normal. From the seventh to the ninth day colic was of increased severity, located chiefly in the epigastrium, where also distention was greatest. Constipation was absolute. The distention was several times relieved by puncture (in the epigastrium) with an hypodermic needle, and morphine was administered here subcutaneously. During this interval vomiting, that had occasionally taken place from the beginning, became fæcal. Pulse, 120 to 126.

On the ninth day consultation was held and prognosis given as very grave. As a *dernier ressort* castor-oil was given by the mouth, in half-teaspoonful doses, three and a half teaspoonfuls in all being administered on that day. The first dejection secured contained balls of fæcal material "as hard as bullets." Colic decreased during the following two days, after which convalescence seemed assured. Three weeks later applications were still being made over the induration in the iliac region.

Eight months after this illness the family travelled to England, the child having had two relapses during this time, but being finally in very good condition of general health. A slight induration behind the ascending colon still remained, of which Dr. Sebold wrote that he did not consider it cause for further anxiety.

On arriving in England he was again ill. Dr. W. B. Cheadle was called in consultation. His physician, Dr. William H. Platt, late of Hampstead, wrote: "I found him suffering from perityphlitis of an extensive character. There was great pain and tenderness in the right iliac region, extending almost to the mesial line; sickness, and a temperature ranging for many days from 100° to 102° F." For ten months he was under medical care before it was deemed prudent to recross the Atlantic. A very slight amount of thickening near the crest of the ilium remained, but he had been free for several months from all local tenderness.

During the following three years his health was good, so that he attended public school. He continued, as always, the object of supervision with regard to habits of personal hygiene, bowels being carefully regulated by food and habit, and medicine was never needed. Two years ago, after wading in cold water, there was a slight return of abdominal pain and tenderness, controlled by a few days in bed, liquid diet, and cold, wet compresses. This returned twice in the spring of this year, no physician being called in any of these illnesses.

Early in June I first saw him, in the fourth recurrence of these symptoms (the third of this year). He had been in bed a day, having liquid diet and cold, wet compresses over the abdomen. His immediate history had been of excellent health, with no constipation. He appeared vigorous, moving about in bed freely; temperature, 99.2° F.; pulse, 80; slight rigidity of abdominal muscles; no distention; slight general tenderness, somewhat greater in the right iliac fossa, and indefinitely in the left umbilical region. A grain of calomel in divided doses, followed by a saline laxative, with continuation for a few days of treatment already mentioned, was all that was necessary. During the next four weeks his health was excellent and weight increased ten pounds. In the relapses and returns while abroad and at home the initiatory pain was in the upper abdomen.

His last illness began on the evening of July 12th. During the afternoon he had worn shoes and stockings

[1] The notes of this case were given before the Rhode Island Medical Society in December. The discussion that followed, by Drs. Cabot, Collins, and Noyes, will be found in full in Transactions, 1894.

thoroughly wet for one or two hours. Some of his recent abdominal symptoms had arisen on apparently similar provocation. After supper, at which he had taken the first small fruit with seeds that he had ventured to eat this season, he had severe pain across the epigastrium and upper umbilical region. Cold compresses were applied over the abdomen. There was much pain and restlessness through the night.

I was called at 4 A.M. I found the patient moving about freely; the sitting or half-reclining position being preferred to the dorsal decubitus (as throughout the illness); respiration markedly thoracic. The pain was a continuous "aching," with severe exacerbations, located as above. There was neither nausea nor retching, but a desire to evacuate the stomach to ease the pain. Examination with special reference to peritonitis and appendicitis was negative except possibly a slight involuntary muscular tension of both recti. Over the seat of pain was tympanites and softness. By drinking warm water a copious vomitus was returned, consisting of wholly undigested milk, raspberries, and bread. The pain was but slightly eased By enema a large soft stool was secured, followed within an hour by a second similar. There had been no previous constipation. The pain being somewhat less and the stomach having rejected a saline cathartic, one-tenth of a grain of calomel with bicarbonate of sodium was administered hourly through the day, and chipped ice and sips of water. Evening temperature was 99° F., and pulse 82. There had been frequent ineffectual attempts at stool, indicative of exaggerated peristalsis.

On the morning of the second day, after a very restless night, pulse was 120; temperature, 99.4° F. There was rigidity of abdominal walls, pain and slight tenderness over abdomen, slight general tympanites except over a small area of dulness, and an ill-defined fulness in the right iliac fossa. Distention was slight. There was an easily compressible prominence in the epigastrium, where pain continued most severe. Emesis had occurred twice since the previous morning, chiefly of water and yellow bile. The patient was bright and vigorous—an exceptional feature of the whole illness—no collapse appearing at any time until toward the end of the operation. Nutritive enemata of peptonized milk were begun, morphine subcutaneously (opium per rectum not having eased the severe pain nor quieted restlessness), with fractional doses of calomel by the mouth.

On the morning of the third day Dr. Robert F. Noyes, of Providence, saw the case in consultation. The night had been restless, with delirium. Pulse was 120, feeble and irregular; temperature, 100° F.; respiration, thoracic. The patient, appearing bright, had the facies abdominalis; tongue dry, with a thin, white fur. There was singultus and constant vomiturition: general abdominal pain and tenderness no more marked over the so-called McBurney's point than elsewhere; an ill-defined tumefaction in the right iliac region, and dulness extending to the linea alba; tympanites over remainder of abdomen, and considerable distention, with an oval fulness above the umbilicus, nonresisting to pressure. The stethoscope applied to abdominal wall discovered apparently complete intestinal paresis. General peritonitis and appendicitis was diagnosticated. The prognosis was considered practically hopeless

In the afternoon Dr. Collins, of Providence, as surgical consultant, saw the case with Dr. Noyes and myself. Through the day twenty grains of calomel in two-grain doses had been given; and every four hours in nutritive enemata one-thirtieth of a grain of sulphate of strychnia, with ten drops of the fluid extract of convallaria. Unsuccessful attempts to relieve distention by soft-rubber tube in rectum and by turpentine in enema had been made. Constipation had been obstinate since the first day. Singultus and vomiturition had ceased; pulse ran from 120 to 130: temperature, 101.2° F. Other conditions were practically as before except that the line of percussion dulness was somewhat extended beyond the mesial line and up to the level of the umbilicus. The conclusion arrived at in consultation was that, on account of the probably septic character of the peritonitis and the grave condition of the patient, operation was not advisable, and prognosis was given as in the morning, the only ground of hope being that the patient had been apparently as ill as this before.

During the following three days (fourth, fifth, and sixth days of the illness) tonic treatment of strychnia, convallaria, and whiskey was pursued, feeding and medication being per rectum and sigmoid flexure, except for occasional small quantities of saline mineral waters, light wines, and egg albumen (raw or predigested) by mouth. Delirium ceased; pulse fell to 95 and assumed a better character; temperature became normal, tongue moist, distention nearly disappeared except the elastic swelling above the umbilicus; tenderness and pain lessened, and area of dulness decreased. Per rectum a small nodular, extremely sensitive mass could be palpated (but not outlined beyond its lower surface) high in the right groin. Urine showed no albumin nor increase of indican. On the fifth day stercoraceous vomiting began, and continued at intervals of six to ten hours up to the time of surgical interference. The gastric distress preceding emesis was shortened by lavage with warm saline solution, it being drunk. This was immediately efficient and more agreeable to the patient than a stomach-tube. It seemed at this point impossible to determine whether the intestinal obstruction was of the functional, adynamic form consequent upon intestinal paresis, or whether it was due to constricting bands, remains of plastic exudate, or to fæcal impaction possibly signified by the dulness in right lower abdomen. The sausage-shaped, easily compressible tumor, across above the umbilicus, suggested that the point of occlusion might be at the splenic flexure of the colon. That it was not below this point had been demonstrated by large enemata and passage of soft-rubber tube.

On the seventh day Dr. Charles Putnam, of Boston, saw the case with Dr. Noyes and myself. It was agreed in consultation that the nature of the obstruction being unknown, continuation of tonic treatment would be proper, while local and general symptoms of acute inflammation progressively subsided, there being a possibility that the obstruction would be relieved with disappearance of distention paralysis. During the next forty hours temperature remained normal; pulse ran between 90 and 100; local meteorism in epigastrium disappeared; the line of dulness receded until the area remained only over cæcum and a portion of ascending colon. General abdominal tenderness was very slight, appearing more localized to the left of and above the umbilicus. Borborygmus and passage of small quantities of gas per rectum testified to return of peristalsis. The general appearance of the patient was bright but weaker. Apparently the obstruction was not to be relieved without opening the abdominal cavity.

On the ninth day, after conference, at which the cause of the obstruction was considered to be probably a band, the product of former serous inflammation, Dr. A. T. Cabot, of Boston, operated, Dr. Noyes and Dr. Charles Putnam also being present. I am indebted to Dr. Cabot for the following account of the operation:

"The patient being etherized, an incision about three inches in length was made under antiseptic precautions, in the median line below the umbilicus. The coils of small intestine presenting were purplish in color and considerably distended. Following these down with the finger, a constricting band was felt close against the spinal column, just above the umbilicus. This point coincided with the one at which the greatest tenderness had been experienced in the palpation pre-

vious to operation. The incision was enlarged an inch and a half upward, avoiding the umbilicus, and the constricted portion of the gut brought into view. The constricting band was made up partly of what seemed to be inflammatory adhesions, with the omentum rolled up and thickened about them. After these had been divided a further band of organized tissue was found, which was tied and divided. The divided end of this gave the suggestion of its being a diverticulum, there seeming to be a little mucous membrane in the stump projecting from the ligature. When this was finally divided, the intestine, which had previously been bound down against the spinal column, could be lifted forward and out of the abdomen. It was at once seen that there was an opening in the intestinal wall close to the insertion of the mesentery. Whether this was an opening from which a diverticulum had been separated, or whether it was an ulcerated opening caused by the pressure of the band, was not at the time clearly made out, as the patient's condition demanded speed of operating and gave no time for careful study of pathological conditions. It seemed probable, however, from an after-consideration of the anatomical conditions, that this was the opening from which a diverticulum had been cut in dividing the aforesaid bands. At the point where this band crossed the intestine there was a very decided narrowing of its lumen, and the walls were very much thickened.[1] The gut above and below was held by an assistant and so compressed as to prevent the escape of fæcal matter.

"A portion of this strictured tissue was cut out in a V-shaped manner, including the opening of the intestinal wall. It being then found that the ends of the intestine were still smaller than was desirable, they were further slit back by a longitudinal incision along that portion of the intestine farthest from the mesentery. The ends of the intestine having been thus enlarged to the full size, the gut was sutured together by an end-to-end suture, two layers of Lembert's stitches, including serous and submucous layers, having been made.

"During all of the manipulation necessary for the intestinal suture, the abdominal cavity was shut off by gauze, so that none of the intestinal contents entered the peritoneal cavity. During the latter part of the operation the patient's condition was far from satisfactory, with cold extremities and requiring constant stimulation by subcutaneous injections; extensive exploration of the abdominal cavity was therefore not deemed advisable in the absence of any indication of trouble.

"A hasty search in the cæcal region detected no enlargement or adhesion there to lead to the belief that there had been former attacks of inflammation in that region. The abdominal incision was quickly closed with a single layer of silkworm-gut sutures, and antiseptic dressing applied."

The condition of collapse was considerable, but the patient rallied promptly and passed a fairly comfortable night with natural sleep. Convalescence was practically uncomplicated. There was no further emesis. β-naphthol was given in the beginning as an intestinal antiseptic. On the third day after the operation a small soft stool passed, neither this nor later dejections witnessing to fæcal impaction. The sutures in the abdominal wound were removed on the eighth and eleventh days. The nutritive enemata were discontinued thirteen days after they were begun, the lower bowel having served this length of time to absorb both food and medicine. Solid food was first swallowed on the twelfth day after operation. The patient was out of bed on the fourteenth day, and left the city on the twenty-first, weighing but three pounds less than before his illness.

[1] "The diverticulum, arising from one side of the ileum, crossed over the bowel and was inserted somewhere posteriorly, as I thought, to the mesocolon close to the cæcum. Its pressure upon the ileum where it crossed was the cause of the obstruction."—Dr. Cabot, *loc. cit.*

Examination per rectum previous to departure discovered no sensitiveness nor tumefaction in the region of the lesion observed in the first week of illness. Up to this date the patient has been entirely free from signs of abdominal disease and reports excellent health.

Symptoms.—On account of the recognized difficulties in the differential diagnosis of certain abdominal diseases, the following tabular statement is of interest, summarizing briefly the chief points bearing upon the present case:

Appendicitis.	Obstruction from Band.	First Five Days of Case.
History of previous attacks.	Of peritonitis.	Of appendicitis with peritonitis, relapses, recurrences.
Onset sudden.	Sudden.	Sudden.
Pain peri-umbilical and epigastric at first; severe, continuous with exacerbations; soon centres in right iliac region.	Referred to seat of obstruction or peri-umbilical, persistent; severe, continuous with exacerbations.	Epigastric and peri-umbilical, persistent; severe, continuous with exacerbations; in twenty-four hours became general; not marked in right iliac region.
Nausea and vomiting coincident with or soon following pain; not prominent as a rule.	From the first frequent and copious, and soon becoming fæcal.	Eleven hours none; emetic first caused; first day once; second day twice (peritonitis developing); third day constant; fourth day none; fifth day fæcal.
Tenderness and tumor in right lower abdomen, almost pathognomonic in male.	None.	First day deep palpation negative; second day dulness, fulness; later per rectum very sensitive tumor high in right groin.
General peritonitis often develops, adding general tenderness, fever, distention, vomiting, intestinal paralysis.	The same.	Fully developed on third day.
Tenesmus not a symptom.	None.	First two days.
Constipation may precede or accompany; may be absolute.	Absolute.	None preceding; after enema normal stools first day; later, absolute.
Prostration and collapse frequent.	Extreme.	None.
Fever prompt; variable.	None at first.	Began within twenty-four hours.

The greater correspondence between the early symptoms and those most pathognomonic of appendicitis is apparent. The history in Germany and England is suggestive in this connection.

The unreliability, however, of the most diagnostic of these signs, tumor and tenderness in the right iliac fossa in the male, is illustrated by a case reported by Fowler,[1] in which there was a point of special tenderness in the right iliac fossa. With the provisional diagnosis of primary appendicitis and subsequent intestinal obstruction, either from intestinal paresis or angulation, the abdomen was opened. There was no evidence of appendicitis, and the obstruction was due to Meckel's diverticulum wrapped around the ileum close to the cæcal valve. Fitz[2] also cites a case of intestinal obstruction, in which an artificial anus was made on the tenth day near the umbilicus, at the exit of a congenital sinus, that had been known to discharge portions of food. On the day after the operation pain, tenderness, and tumor were distinct in the right groin. At the autopsy a diverticulum was found, arising from the ileum, four feet above the cæcum, and extending to the navel. No cause for the symptoms in the iliac region was noted (Homans). Dr. Cabot,[3] in discussing the present case, refers to another cited by Fitz,[4] where a diverticulum and cord of vitelline origin were attached to the cæcum posteriorly, serving as a noose to constrict the intestine, producing obstruction. Such attachment would be apt to cause symptoms referable to the cæcal region, and "clinically strongly suggestive" of appendical disease.

The fact that the constricting band, while closing the lumen of the bowel, did not interfere with the mural circulation, explains the absence of gangrene. It is not illogical also to infer that the freedom from collapse and prostration was partially owing to this fortunate condition.

Treatment.—The satisfactoriness of milk and egg (fats and albumin), instead of fluid preparations of

[4] Loc. cit., p. 46.

beef (extractives chiefly), where alimentation is of critical importance, was evidenced in this case.

Intestinal antisepsis in abdominal disease is a point in treatment to which Dr. J. William White has recently called attention, particularly with reference to appendicitis. Antisepsis by the administration of calomel in small and considerable quantities, and by the use of β-naphthol, was probably not the least important of the factors favoring recovery after the operation.

The prompt and marked effect of a large dosage of calomel, administered at the height of sthenic inflammation, is again illustrated in this case of intestinal obstruction.

Pathology.—Meckel's diverticulum occurs in about two per cent. of individuals. Osler[1] reports finding twelve in five hundred and fifty autopsies. It is of interest chiefly on account of its being a cause of intestinal obstruction. Fagge[2] reports the number of obstructions from this equal to the number from all other bands. The mechanical conditions are the same in either case.

During a portion of the first month of intra-uterine life the nourishment of the fœtus is probably derived from the umbilical vesicle by means of the umbilical (vitelline, omphalo-mesenteric) duct which communicates with the primitive intestine at a point that afterward is in the lower third of the ileum, usually about three or four feet from the ileo-cæcal valve in the adult. Below this point the large intestine and lower ileum develop; above it, the remainder of the alimentary tract. The duct is accompanied by omphalo-mesenteric blood-vessels, arterial and venous. Early in the second month closure of the plates forming the abdominal wall divides these canals into an extra-abdominal segment and an intra-abdominal portion. Both segments atrophy with the establishment of placental circulation, the remains of the former being found as a cord lying in Wharton's jelly, in the umbilical cord. The intra-abdominal portion passing from ileum to umbilicus sometimes remains as an open canal (fistula) or as a cord. It usually ruptures and entirely disappears. It may form a cyst. The duct may remain patulous for a short distance from the ileum, forming the *diverticulum ilei* (Meckel's) with sometimes the cord-like remains of the vessels hanging free from its tip or connecting it with umbilicus; with or without these the diverticulum may be found connected to mesentery, omentum, intestine (large or small), or parietal peritoneum. Such connection has almost universally been considered of inflammatory origin; but by reports of examinations of various specimens Fitz[3] demonstrates that not infrequently it is an omphalo-mesenteric vascular connection; first, negatively, by the absence of inflammatory tissue at the junction; secondly, by actually tracing a vessel, pervious or closed, from diverticulum to umbilicus or into mesenteric artery (of vitelline origin), the tip of diverticulum being oftenest found connected with the mesentery of the ileum. Thus there may be a congenital band, loop, or ring as a predisposing cause of obstruction. Pye-Smith[4] reports a diverticulum coming off from the ileum near the mesentery, passing back through an opening in the mesentery, and closely encircling the bowel around to a point about half an inch above the same opening; here its tip was firmly connected to mesentery.

Attachment of the distal end of the band to meso-colon or in the neighborhood of the cæcum, as it was thought to be in this case, is among the rarest of the varieties reported. This was one of the points that there was not time to investigate. Dr. Cabot believes it quite possible that the attacks diagnosticated appendicitis were due instead to inflammation about the band, indicated by false membranes and adherent omentum found there, the attachment near the cæcum accounting for special symptoms of appendicitis; these repeated attacks of inflammation leading to gradual contraction of the band on the intestine, and finally to complete obstruction, and causing a chronic thickening in the walls where it crossed.

It is also possible that in Germany primary appendicitis followed by peritonitis caused inflammation around and constriction by the diverticulum on about the sixth day, as the history suggests, "and then by chance, or by castor-oil, or in spite of cathartics, the diverticulum loosened, the bowel became pervious, and the lad recovered." Later, by conservative treatment in Germany and England, gradual reversal of cause and effect was brought about, the band becoming the threatening lesion, and in the attacks of inflammation relighting the old cellulitis in the right iliac fossa.

Dr. Noyes queries: "If there has been nothing in this case but Meckel's diverticulum, how do we explain 'the induration behind the ascending colon,' . . . the 'thickening above the crest of the ilium,' . . . 'the mass felt by rectum in the last illness, the dulness on percussion in the right iliac fossa, extending to the umbilicus and to the mesial line?' If these [latter] signs were dependent upon fæcal accumulation, what became of it? . . . It was almost entirely gone before an alvine evacuation could be effected."[1]

In conclusion, if one end of the constricting band were attached near the cæcum symptoms of appendicitis might be produced; even if elsewhere, to reason from the Homans case, such symptoms might also occur; and "as there is usually but one major cause," although not necessarily so, it is possible to infer that there has been no appendicitis in this case. Proof can come only from direct examination of the vermiform appendix.

PRE-THYROID CYST.

By F. W. HIGGINS, M.D.,

CORTLAND, N. Y.

The case which gave the title to this paper was of a gentleman thirty-two years of age, who consulted me in regard to his neck two months ago. While in college, eleven years before, in a scuffle, he was quite severely choked by a fellow-student. A short time after he began to notice that the "Adam's apple" was enlarging. He consulted several physicians about it, but was advised, as he valued his life, to allow no operation to be performed upon it. After reaching a size which rendered it plainly noticeable, it remained for several years unchanged. For the last year, however, he and his family had marked an increase in its growth, most visible upon the right side. The symptoms were practically nil. Examination showed the thyroid cartilage hidden by a fulness which gave to the finger the impression of a cystic growth. I supposed that it consisted of an enlargement of the bursa situated between the shield of the larynx and the skin, and advised its removal.

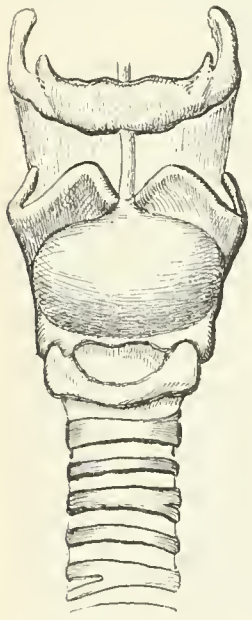
As soon as his business would allow I did operate, assisted by Dr. F. D. Reese; Dr. J. W. Whitney giving the anæsthetic. To my surprise, the growth lay beneath the sterno-hyoid and thyro-hyoid muscles, directly upon the perichondrium. It was a moderately thin-walled cyst, which ruptured in shelling it out from under the muscles. It contained about two drachms of fluid and flocculi having the appearance of thin buttermilk, the flocculi probably originating from degenerated epithelial contents. There was no firm attachment except a pedicle from the upper side, which extended behind the hyoid bone into the substance of the root of the tongue, maintaining, as far as followed, a uniform diameter of about $\frac{3}{16}$ inch. Finding that it was not per-

meable when tested with a probe, it was cut off and the wound dressed without drainage. I have made a rough pen-and-ink drawing to represent the position of the cyst. Recovery has been uninterrupted.

This case assumed a most interesting aspect when we began to study the origin of such a cyst. It is without doubt a traumatic cystic enlargement of a persistent portion of the fœtal ductus thyreo-glossus or canal of His.

This structure, which, so far as I know, was first described by His in that portion of his "Human Embryology" published in 1885, and still more fully written of in the *Archiv für Anatomie* for June, 1890, is a duct leading from the pharynx, through the root of the tongue, in front of the larynx to the thyroid gland. The thyroid gland in its origin in the fœtus of 2.5 mm., is a simple evagination from the front of the pharynx. Becoming constricted at its upper end by the continued growth of the segments of the tongue, the body descends in front of the developing trachea, obtaining the shape of a Florence flask with a constantly lengthening and narrowing neck communicating with the pharynx at its point of origin. The permanent portion of the thyroid becomes solid, the duct leading to it having obtained its maximum at the fifth week of fœtal life, atrophies, until at the eighth week it has entirely disappeared in all but exceptional cases. The foramen cæcum, at the apex of the triangle made by the circumvallate glands of the tongue, marks the remains of the upper end of this duct. Its depth varies within wide limits. His has recorded cases in the cadaver in which it was pervious as far as the hyoid bone.

A very interesting case was published by C. F. Marshall, in the London *Journal of Anatomy and Physiology* for October, 1891. In this there was discovered in the autopsy of a child a persistent canal of His. A fine plate illustrating the condition is reproduced in the "Annual for Universal Medical Sciences" for 1892, vol. v.



That persistence of this canal is rare, is shown by the investigations of Kanthack, who examined unsuccessfully 160 cases with reference to this point. He is, indeed, inclined to doubt its possibility. However, we all know the little value of negative evidence.

His is of the opinion that the later development of the hyoid bone takes place across the path of this canal, and assists in obliterating it. In our case, however, the pedicle bent sharply backward at the notch above the thyroid cartilage, then behind the body of the hyoid, tension showing its attachment to be in the substance of the tongue, into which it disappeared after section.

Last October Mr. Dundas-Grant was kind enough to ask me to assist in operating on a case of sinus, presumably caused by a persistent ductus thyroid glossus at the Central London Throat Hospital. This led to the body of the hyoid, but it could not be traced beyond.

So far as I have been able to find by consulting the literature at my command, and communicating with Dr. Billings or my friends, this may be the first cyst of the neck to which the remark of His can be applied. He says: "It will be a matter for further investigation how far the lingual canal may be the origin of peculiar growths."

Cysts and sinuses of the brachial clefts are now well understood. Growths from the lingual canal have been only recently recognized.

Pre-thyroid cysts seem not to have been well described. The laryngologists have record of intra-laryngeal growths of every type, but do not trouble themselves with cysts lying in front of the larynx.

Differential diagnosis must be difficult before examination. Cysts of the bursa would probably appear more superficial, more prominent, not so broad, as this case bound down by the muscles.

Adenoid cysts, again, which may appear anywhere on the surface, could not develop beneath the muscular structures. In this connection it is well to remember that the bones and muscles develop from the mesoblast later than the fifth week.

A bursa occurs between the thyro-hyoid ligament and the body of the hyoid bone. I do not know that any case of its enlargement is recorded. On section, or by the exploring needle, its serous contents would distinguish from the epithelial growth under consideration.

It is probable that the cyst in the case here described was in thought confused with goitre or enlargement of the thyroid gland. A moment's consideration of its high location should serve to differentiate. Cases of small supernumerary thyroid glands have been recorded. Such an one might be found lying in front of the thyroid cartilage.

There would seem to be no marked complication or danger in operating upon any of the adventitious growths in this region.

A CASE OF HODGKIN'S DISEASE.

By CHARLES E. NAMMACK, M.D.,

VISITING PHYSICIAN TO THE GOUVERNEUR HOSPITAL, NEW YORK.

Inasmuch as but four cases of this disease were reported in English medical literature during the year 1893 (Index Medicus), opportunities for its observation outside of the large medical centres must be rare, and the recital of the following instance may be justifiable. No attempt will be made to speak of the disease by any other of its numerous synonyms, as there is already much confusion in this very name-ridden subject.[1] Clinical observers have christened and rechristened it, and pathologists have bestowed on it a bewildering wealth of terms. However objectionable may be the naming of a disease after an individual, the term Hodgkin's disease still conveys to the general practitioner the clearest mental picture of the condition described.

Joseph W——, twenty years of age, native of Austria, eleven months in the United States, entered the service of my colleague, Dr. Robert J. Carlisle, at the Gouverneur Hospital, on July 21, 1894. His family history was good. Father and mother living and healthy. Six brothers and sisters, of whom four died in infancy of acute diseases and two are living and well. No history of tubercle or syphilis in ancestors. Father says that Joseph had measles and chronic nasal catarrh. Ten months ago the boy began to experience pains in the soles of feet, extending to legs and arms, and finally to head within one week of first perception of the pains in feet. Headache has continued with more or less severity since. During the first four months he had chills every day with fever at night. It is probable that during this period the boy was insufficiently fed and lived in the crowded tenements surrounding the hospital, as his parents belong to the "sweater" class, a knowledge of whose wretched mode of life would astonish our more fortunate citizens. We have, then, as etiological factors in the case, privations and chronic nasal catarrh.

Six months ago, a lump appeared on the right side

[1] Medical Record, Editorial, October 10, 1891.

of his neck, quickly followed by others on the chest, limbs, and head. That on the neck attained the size of a baseball, as did also two on the chest, and one on the forehead. The others were of various smaller sizes, and are fairly well shown in the accompanying illustration. Exophthalmos of the right eye existed, with complete loss of vision, probably due to pressure of an enlarged gland in the orbit, but this we were not allowed to verify post mortem. In this condition he was admitted to the hospital.

Physical examination of the lungs and sputum was negative. The spleen was not demonstrably enlarged. Liver dulness normal in extent. Urine was abundant, sp. gr. 1.010, alkaline, no albumin, no sugar. Genital organs poorly developed. Appetite fair, thirst marked, no stomatitis, no submucous hemorrhages, no tonsillar enlargement. One gland in roof of mouth is markedly enlarged and projects into the mouth cavity to considerable extent. Respirations varied from 16 to 24. Pulse from 94 to 140. Anæmia was one of the most conspicuous features of the case, but it is a matter of regret that the present hospital facilities did not permit an accurate and complete blood examination. Marked depression of spirits, stupidity almost amounting to idiocy, and excessive languor were evidences of a poorly nourished brain. Temperature was almost continuously elevated until the last five days of life, when it became subnormal.

On July 30, 1894, a gland was cut from the abdominal wall and sent to the New York Hospital pathological laboratory for examination. Dr. Frank Abbott, Jr., reported that its microscopical structure was that characteristic of adeno-sarcoma. The patient died August 9th, the duration of his illness, from the time enlargement of a gland was first noticed, having been seven months. Permission to make a complete autopsy could not be obtained, but we were allowed to make an abdominal incision and remove the spleen, kidneys, liver, heart, and an enlarged lymphatic gland, measuring 7 × 7 × 3 centimetres, which projected from the second and third right costal cartilages into the right pleural cavity. The spleen was slightly enlarged, pale in color, firm in consistency, and, on section, showed increase of fibrous tissue. The kidneys were abnormally large in size, greenish color, markings indistinct, and capsules adherent. There was a nodule in one of the kidneys, just under the capsule, about one-half centimetre in diameter. Under the microscope this nodule was shown to be sarcomatous. The heart was very small, muscle pale, valves normal. The aorta showed small patches of atheroma. The liver was normal in size and showed increase of fibrous tissue. The gall-bladder was distended, the walls being very thin.

In the diagnosis of this case, tuberculous polyadenitis was first thought of, and excluded. Although a blood examination was not made, the predominance of the lymphatic element, with absence of hemorrhages, diarrhœa, and of enlargement of the spleen, was considered sufficient to exclude leukæmia.

The generalized distribution of the enlarged glands, and the absence of invasion of contiguous structures—the swellings remaining throughout indolent, isolated, and painless—served to exclude true local, non-infective lympho-sarcomata.

That Hodgkin's disease is an infectious process, Osler[1] thinks there is now little reason to doubt.

Dreschfeld[2] looks upon it as a specific inflammatory growth due to a specific infective agent, which agent remains yet to be found. Almost invariably the termination is fatal. The treatment by arsenic and improvement of the patient's general surroundings can only postpone the end.

Black[3] speaks enthusiastically of the exhibition of methyl violet as a remedy of the greatest value, especially when arsenic cannot be taken.

Bloomfield[4] narrates a case in which the feeding of a sheep's spleen, lightly grilled, ameliorated the general condition, and made death easier. In this case the patient's spleen was markedly enlarged.

Duplay[5] recites an interesting case in which tuberculous adenitis coexisted with lymphadenoma.

Delbet[6] gives the reasons why malignant glandular lymphadenoma ought to be withdrawn from the group of neoplasms and placed in that reserved for infectious diseases.

A. A. Kisel,[7] a Russian writer, reports five personal cases, and gives the results of treatment by Fowler's solution in seventy cases gathered from the literature, as follows: 19 cured after one to six months' persistent use; in 14, temporary improvement; in 37, no benefit.

H. Barbier,[8] in an article on the development and infectious nature of pseudo-leukæmia, gives the reasons why he is convinced that the last word in explaining the disease will belong to bacteriology.

The writer is indebted to Dr. Boleslaw Lapowski for abstracts of the recent foreign literature of the subject.

20 East Twenty-fourth Street.

FOUR CASES OF CŒLIOTOMY FROM A SERIES OF TWENTY-FIVE, WITH A SKETCH OF THE AFTER-TREATMENT.

By ROYAL P. WATKINS, M.D.,
WORCESTER, MASS.

The following cases are selected from a series of twenty-five consecutive cœliotomies performed in Bellevue Hospital during my service as house physician, from April 1, to October 1, 1894. It seemed impossible to report them all in detail, and I have chosen these four, the first two because of their intrinsic interest, and the other two because they are fair average examples, one of the acute and the other of the chronic form of tubo-ovarian disease included in the series.

Seven of the series were supra-pubic hysterectomies for either fibroid or carcinomatous degeneration, all but two of them, however, being complicated by disease of one or both tubes and ovaries.

Fourteen of the operations were performed by Dr. R. H. Wylie, nine by Dr. W. Gill Wylie, and two by myself. There were no deaths.

Case I.—Admitted April 19th. Has had three children, last one eighteen months ago. Has been nursing this child up to date and has not menstruated since its birth. About April 10th she began to have severe bearing-down pains in hypogastric region, constant and grinding in character, with backache and additional pains in the left iliac region. She began at the same time to pass blood from the vagina, and thought she was menstruating. This continued for about a week, when the pain became more severe and she began to pass blood in large clots. She finally became alarmed and walked to the hospital nine days after the onset of the symptoms.

Examination by vagina showed a soft, doughy mass in the right fornix, slightly movable with the uterus and seemingly adherent to its right corner.

On the day after admission flowing stopped and pain diminished somewhat. The patient was kept in bed and watched carefully for four days. Temperature was normal, pulse fairly good, no visible hemorrhage, and pain continued to diminish. The mass in the pelvis seemed to be increasing in size, however, and on April 23d she was operated upon.

A mass was found on the right side about the size of an orange. It was closely adherent to the uterus and to the pelvic wall, and proved to be a hæmatoma in the broad ligament covering a rupture in the Fallopian tube. The blood in the tumor was black and thickly clotted, and the tube was filled with the same material. The mass with the tube and ovary were removed. The appendages of the opposite side were normal and were not disturbed.

The sac having been ruptured during its removal, the abdominal cavity was irrigated with water at 112° F., and a Wylie glass drainage-tube inserted around which the wound was closed.

On the day following operation the patient developed œdema of the lungs from some unknown cause, and was in a very precarious condition for nearly twenty-four hours. She finally rallied and recovered without further interruption. Discharged May 23d.

Case II.—Admitted June 29th. Dates her trouble from birth of child six years ago. Since that time has had severe sharp pains during menstruation over hypogastric and both iliac regions, and extending down the thighs. Menstruation has been regular and can get no history indicating pregnancy at any time during the last six years. Patient is anæmic and emaciated, and runs an irregular temperature between 99° and 101° F.

Operation, July 5th. The omentum was found directly under the abdominal incision, was adherent to the intestines and to the fundus of the uterus, and was very soft. It was freed from its adhesions and its bleeding points ligated with silk. The pelvis was then found to be filled by uterus, appendages, and small intestine, all matted together by a thick hemorrhagic exudate, which had become partly organized and was very firm. The tubes and ovaries were separated from the mass with great difficulty, and removed. The left ovary was cystic, and the tube the seat of an ordinary pyosalpinx. The right tube was distended to about the size of an egg, with the same hemorrhagic material which formed the adhesions in the pelvis. There was no rupture of the tube and its fimbriated extremity was occluded. All the adhesions were then broken up and the greater part of the exudate removed, being torn away in large flakes. Irrigation and drainage were used as in Case I.

Patient gained flesh and strength very rapidly, and was discharged four weeks after operation, well nourished and with good color.

Case I. was undoubtedly a tubal pregnancy with rupture of the tube and hemorrhage into the broad ligament.

In Case II. there had evidently been a hemorrhage from the free end of the Fallopian tube into the peritoneal cavity, with subsequent closure of the tube, but the history gives us no light as to its cause. It may have been a tubal pregnancy also.

Case III.—The origin of the infection in this case is obscure. I believe the history to be reliable.

The patient has never skipped a menstrual period, and has never had any symptom of vaginitis. Menstruation has always been regular as to periodicity, duration, and amount of flow, and has never been preceded, accompanied, or followed by pain. Ten days before admission, and two weeks after her last menstruation, she took a large dose of Epsom salts. This was followed by a large number of movements, and a vaginal discharge similar to the menstrual flow which continued for a week. Then there came a severe flooding, the patient losing so much blood that she fainted. She was brought to the hospital two days later, having in the meantime developed severe sharp pain with slight tenderness in the lower regions of the abdomen, more severe in the left iliac. The bleeding was not alarming, and was controlled by hot douches, cannabis indica, and rest in bed. Examination revealed a sensitive mass on each side of the movable uterus.

The pain and tenderness remained about the same, and the temperature ranged between 99° and 102° F., during the three days she was kept under observation.

On June 16th the abdomen was opened. The pelvis was found to be shut off by fresh adhesions, which were easily broken up. There was a small amount of free pus in the bottom of the pelvis which had evidently escaped from the right Fallopian tube. This tube was distended with pus and its fimbriated extremity not entirely occluded. It was clasped with forceps to prevent further leakage, and the tube and its ovary, which was also purulent, removed.

The left tube was even more distended with pus than the right, but was occluded. The ovary contained several small cysts and was removed with the tube. Irrigation and the glass drainage-tube were used as in the previous cases.

After twelve hours, at 1 A.M., June 17th, the drainage-tube was removed. At 9 A.M. the temperature had gone up to 102.4° F., and a smaller glass tube was inserted. Temperature then fell gradually and became normal on the 19th. A slight amount of sero-purulent material continued to drain through the tube, and it was replaced by a rubber one, which was gradually shortened, and removed entirely on June 28th. The wound healed rapidly, and patient was discharged August 3d, after being up and about the ward for two weeks.

Case IV.—Admitted April 30th. Has had one child eighteen months ago. No miscarriages. No history of vaginitis. Symptoms began one month ago. Patient took a cold bath while menstruating and caught a severe cold. Had no effect on duration of menstruation, nor on amount of flow, but directly after bath began to suffer with severe sharp pains in both iliac regions, associated with general abdominal tenderness. These symptoms have continued and confined the patient to her bed ever since. Has had some vesical tenesmus. Bowels regular. Temperature, pulse, and respirations normal.

Examination showed a fixed uterus with firm masses on either side bound down by adhesions. Condition remained the same until operation, May 7th.

On opening the abdomen a considerable amount of clear serous fluid welled up from the general peritoneal cavity. The cavity of the pelvis was completely filled with one mass of adhesions. The coils of intestine were bound to each other and to the bladder, uterus, and tubes. The uterus was also adherent to the bladder. The adhesions were very firm and had evidently begun to form at a period considerably antedating the beginning of the symptoms. After considerable difficulty they were broken up without damage to the intestines. The tube and ovary of each side were freed, tied off, and removed. The tubes were distended with pus and there was pus in each of the ovaries. One of

the tubes was ruptured during the manipulations, and a small amount of pus escaped into the peritoneal cavity.

Irrigation and a drainage-tube were used in this case also, the tube being removed after eighteen hours. Patient's highest temperature after operation was 99.3° F., on the evening of the day following. Discharged June 9th.

A sketch of the after-treatment in these cases may be of interest.

The patients, on being removed from the table, were put in bed with hot-water bottles in the usual way. If stimulation was thought necessary they were given an enema, immediately after the operation, of :

Beef peptones	℥ ss.
Brandy	℥ ss.
Salt	ʒ j.
Water	ad ℥ iv.

In extreme cases, tincture of digitalis, ♏x.–xv., was added. If subsequent stimulation was needed, it was given in the same way, the frequency of repetition and the amount of brandy and digitalis being regulated according to the case. Occasionally strychnine sulphate, $\frac{1}{30}$ to $\frac{1}{15}$ grain, was given hypodermically in addition ; or, if the enemas were not retained, the brandy or digitalis or strychnine, or all three, were given hypodermically. In most of the cases no stimulation was required. Very rarely it was necessary to give opium. When necessary, ♏x. to xv. of the deodorized tincture were combined with the enema. None was ever given after the first twelve hours.

As soon as the gastric irritation had sufficiently subsided, usually in from six to eight hours, hot water was given by mouth, beginning with ℥ ij. every half-hour. The amount was gradually increased up to ℥ j., when ice-water, Vichy, carbonic, or cracked ice was substituted, or the hot water continued if the patient preferred it. The amount of these was gradually increased to ℥ ij., and given then every hour. This process usually extended over about eight hours, or until the stomach would bear milk and lime-water. This was given at first in ℥ ss. doses every half-hour. The amount was gradually increased and the interval lengthened, so that by the night of the day following operation they took ℥ iv., vi., or viii., every two, three, or four hours, as seemed best, with any of the other fluids mentioned in small amounts, p.r.n. If vomiting occurred, everything was stopped for one hour, and another beginning made on hot water. In some cases kumyss, beef-tea, or chicken-broth with the fat carefully removed, were substituted for the milk.

The fluid diet was continued until the bowels were moved, on the morning of the third day. The first solid food was dry toast and a boiled egg. After making sure that the bowels would act properly, the diet was rapidly extended, and by the end of a week or ten days was practically unrestricted.

In the majority of the cases, on the morning of the third day, Epsom salts and Seidlitz powder, ää ℥ ss., was given in one dose, or the same amount in four doses, a half-hour apart. In cases where the breaking up of adhesions left a very extensive raw surface, the bowels were moved on the second day. Not infrequently the cathartic had to be repeated or a turpentine enema given. The bowels were then moved every day.

Any tympanites or colicky pains which occurred before the bowels were moved were usually relieved by the rectal tube.

The dressing of the wounds required very little attention. When no drainage-tube was used the original dressing was, as a rule, not disturbed until the stitches were removed. When a tube was used a fresh dressing was applied on its removal, and left until the removal of the stitches. In all but three of the cases the union was by primary intention. In each of these three a drainage-tube was left in place for more than three days, and left a sinus which healed from the bottom by granulation.

The drainage-tubes were exhausted by means of a glass syringe with a rubber tube attached small enough to go inside the drainage-tube easily, and long enough to reach to its bottom. The dressings were so applied that the tube was covered by a piece of bichloride gauze which could be removed without disturbing the rest of the dressing. The tube was exhausted every half-hour for about two hours, and the intervals then lengthened according to the amount of fluid obtained. Each time the amount was measured and its character noted. In most of the cases I was able to take out the tube in from eight to twelve hours. The sucker was always boiled each time before using, and every precaution taken not to introduce sepsis with it. The stitches were, as a rule, removed on the tenth day.

The patients were kept in bed for three weeks, and then, after being about the ward for a week, were discharged.

The most constant difficulty experienced in the after-treatment was in moving the bowels, and its importance is testified to by the fact that after the bowels were opened any tympanites or elevation of temperature that may have been present before subsided, and the patients invariably became comfortable, and progressed rapidly to recovery. Obstinate vomiting occurred in a few cases, but was overcome by giving the stomach complete rest (for two days in the worst case) and feeding by rectum.

58 Pleasant Street.

Progress of Medical Science.

Tongue Traction.—Laborde reports a new and striking case of the value of his method of lingual traction. A child, born apparently dead (with the aid of forceps), was treated for ten minutes by rhythmic traction of the tongue, with complete success. The doctor was then obliged to turn his attention to the mother. Returning to the child, it was again apparently dead. All the usual methods of resuscitation were tried—artificial respiration, friction, etc.—without avail. Rhythmic traction of the tongue restored it in six minutes. Tarnier, in commenting on the case, considered the method more generally applicable than insufflation.—*Semaine Médicale*, December 5, 1894.

Neurasthenia in a Boy.—Levillain reports a case of neurasthenia, of the Beard-Charcot type, in a boy of twelve years, following severe and persistent headache. On examining the patient's head a depression was found on the left parietal bone, 8 mm. deep, 5 mm. broad, and 9 mm. long. As the headache was almost uninterrupted, while the other symptoms yielded to treatment, and was accompanied with insomnia and vertigo, the depressed portion of the bone was elevated ; no lesion of either meninges or cortex was discovered. Complete cure followed in fifteen days, both local and general symptoms disappearing.—*Journal de Médecine de Paris*, December 2, 1894.

Ovariotomy During Pregnancy.—Before the session of the Vienna Medical Society held on November 23d, a patient with the following history was presented by Dr. Lotheisen : A peasant woman, aged forty-four, complained of constipation for two years, and obstipation for three weeks. She was referred to Professor Gussenbauer for operation for intestinal occlusion. A tumor of the size of a fist was felt per rectum at the upper level of the sacrum ; the uterus was enlarged and reached above the symphysis. At the operation the uterine tumor was found to be a pregnancy ; the left ovary was much enlarged and twisted on its pedicle, so that it lay behind the sigmoid flexure ; the right ovary

was cystic. Both ovaries were removed. Shortly after the operation defecation occurred without assistance, and the course of the pregnancy was uninterrupted and normal. The left ovary was found to be carcinomatous, the right was cystic, and contained the corpus luteum.—*Wiener klinische Wochenschrift*, November 29, 1894.

The Adrenals and Intestinal Peristalsis.—Pal reports an interesting series of experiments in extirpation of the adrenal bodies, tending to refute Jacobi's position that in them may be found the inhibitory centre for the intestinal peristaltic movements. Pal concludes that the adrenals have no special importance for the life of the animal, even in dogs ; that they cannot be regarded as inhibition centres for peristalsis ; and that the only immediate effect of their extirpation is a severe disturbance of nutrition, which, however, the animal is capable of surviving.—*Wiener klinische Wochenscrift*, November 29, 1894.

Polarization of Saccharine Urine.—Pansini has an important paper on urine polarization, based on two hundred and thirty specimens obtained from Senator's clinic. Urine containing albumin or sugar is lævogyrate in proportion to the amount of the abnormal ingredient. The greatest rotation to the right was obtained in a specimen from a case of icterus. Apart from diabetic and albuminous urine, the rotation has no constant proportion to the elements contained, but the author thinks that by this method we can recognize minute quantities of albumin or sugar more readily than by chemical tests.—*Berliner klinische Wochenschrift*, December 3, 1894.

Gastroplication. — Under this name, Dr. Joseph Brand has recently described a new operative procedure for the treatment of gastric dilatation. Although devised as long ago as 1889, it was not until February of this year that he had an opportunity of putting it into practical execution. Gastric dilatation is usually due to some form of stenosis at the pyloric orifice, either resulting from new growths, cicatricial tissues, or adhesions, and the aim of surgical procedures has been the removal of the cause of the obstruction. Much has been accomplished in this direction by the exsection of the cicatricial tissue or by resection of the pylorus, and the surgeon can point with pride to the successful results obtained in many of these cases by operative means. There are some cases of gastrectasia, however, in which, after all medical treatment has been exhausted and laparotomy has been resorted to, none of the above lesions can be discovered, and the operator is obliged to close the abdomen without having made an effort to relieve the dilatation. It is for this class of patients that Dr. Brand recommends his operation, which has for its object the diminution of the size of the stomach by the formation of a fold and suture of its peritoneal and muscular layers. This procedure has been successfully performed in the case of a female patient suffering from extreme dilatation of the stomach, according to the following technique : The abdomen was opened by an incision eight centimetres in length and parallel with the border of the ribs on the left side. The stomach was then sought for, eventrated by slow traction, and the pyloric region carefully examined. No tumor, cicatricial deposit, or adhesions could be discovered at this place, but a distinct flexion had resulted in consequence of the sagging down of the greater curvature. The anterior stomach-wall was then folded inward and sutured in a transverse direction, and to the right and left of the transverse fold a longitudinal fold was formed in like manner. The same proceeding was carried out on the posterior gastric wall, which was rendered accessible by making several slits through the great omentum, through which the organ was drawn. It was found easy to lift the muscular and peritoneal layers from the mucous membrane, which could be felt as a thick seam. Over two hundred sutures of catgut and silk were inserted, and the stomach was then returned to the abdominal cavity. Aside from the wounding of an arterial twig of the arcus vasculosis during the insertion of sutures in the posterior gastric wall, no accidents were encountered during the operation, which was followed by a most rapid recovery.—*International Journal of Surgery.*

Differential Diagnosis between Pulmonary Syphilis and Pulmonary Tuberculosis.—Dr. Rendu, at a recent clinical lecture, presented an old woman who had for a long time been emaciated and cachectic, but without fever (*The British Medical Journal*). The symptoms were ill-defined : some pain, stiffness of the limbs, without marked weakness or paræsthesiæ, dyspnœa on exertion, and for a short time a dry cough without expectoration. The respiratory and auscultatory phenomena were found normal anteriorly, but behind there was dulness over the right apex, with roughened, prolonged expiration. There was a loud, rough, systolic murmur, together with a softer and more superficial one, but no symptom of cardiac insufficiency. The arteries were apparently healthy, the liver normal in size, and there was no albuminuria. There was a diffuse and characteristic syphilitic melanodermia, and iritis of two years' standing, nocturnal bone pains, and headache. Her only previous illness had been measles. It was pointed out that against tuberculosis was (1) the long duration, (2) the absence of expectoration, of râles, and of concomitant symptoms. Syphilis does not usually attack the apices, although cases of this occurrence are recorded. Syphilis and tuberculosis may occur in association, and tuberculosis may attack a lung previously syphilitic. From the absence of a history of acute pneumonia an indurating pneumonia could here be excluded. The attack of measles was not considered an adequate cause. As there were no other etiological factors, the changes in the heart and lungs were probably syphilitic. Great improvement followed the exhibition of mercury and iodide of potassium.

Examination of Internal Organs.—Dr. Bendersky discusses his method of auscultatory percussion as applied to determine the limits of the thoracic and abdominal organs. He says that in respect to the stomach it gives the best results. A soft stethoscope is placed over the organ to be examined. When the lower limit of the stomach is reached, the percussion note is either but faintly or not at all heard. Lower the note of the colon can be made out, and it is said that it is possible to ascertain the width of the transverse colon, and thus to recognize when it is dilated. The upper limit of the stomach can only be relatively determined. In some cases the boundaries found for the liver and spleen have been ascertained to be correct after death. Fluid in the abdomen has been found to extend one and a half to two fingers' breadth higher than was indicated by ordinary percussion, and in the same way the cardiac dulness has been made out to be larger. Renal percussion may also thus give more accurate results. The author concludes that the boundaries, especially of the abdominal organs, and particularly of the stomach and parts of the intestine, can thus be satisfactorily ascertained. The method is specially useful if the observer be slightly deaf. The number of cases in which gastric dilatation has been incorrectly diagnosed will be diminished by this method of examination. The author describes and figures a collective stethoscope capable of being used by a number of observers at the same time.—*Wiener medizinische Wochenschrift.*

Diagnosis of Pyloric Tumors.—Dr. Rosenheim refers to the restoration of the motor (but not chemical) functions of the stomach after pylorectomy, and he illustrates it from two cases operated on by Hahn three and

a half years and three months ago respectively (*British Medical Journal*). In the diagnosis the symptoms due to pyloric obstruction are noted. Rare tumors not directly at the orifice may cause obstruction by spasm. Palpation will decide the position. The tumor may be displaced to the right, more often to the right and downward, but sometimes to the right and upward. The author quotes another of his cases in which Hahn found an hour-glass contraction due to malignant disease. Gastro-enterostomy was performed. The author then discusses at some length the question of adhesions to the liver and pancreas as shown by the movement of the tumor. This is obviously a most important matter in the question of operative treatment. Tumors of the stomach, intestine, and omentum can often be prevented from ascending during expiration if they are fixed with the hand at the height of inspiration. The author, however, cites a case in which this movement could not be arrested, and yet at the operation by Hahn no adhesions to the liver were found. There were adhesions to the pancreas, and gastro-jejunostomy was performed. If the movement of the tumor upward is very free, the latter may disappear behind the liver edge. Examination should be made in the knee-elbow position. Pyloric tumors move to some extent with the liver when they have been developed in a normally placed organ. They can be more readily diagnosed in women, in whom displacement of the stomach occurs more frequently. Often the presence of a tumor is not necessary for diagnosis. In one case a tumor could not be felt even under the anæsthetic, yet a malignant ulcerating surface the size of a two-mark piece was found at the operation. The patient died of hemorrhage from a stitch-hole in the stomach. The author thinks that, although palliative treatment can improve the condition of the patient, yet in future operative treatment will be the chief one in the majority of these cases.

Sparteine in Chloroformization.—In a communication to the Société de Biologie, P. Langlois and Maurauge call attention to the fact that sparteine, associated with morphine, is a powerful stimulant to the heart during chloroformization. The authors first experimented upon rabbits and dogs. Chloroform was administered to these animals while under the influence of sparteine, and although the anæsthetic caused an arrest of respiration, the heart, disturbed at first, rapidly resumed its normal rhythm. On the sparteinized dog, the arterial pressure remained high even during a profound chloroform narcosis. Sparteine was then tried in the human being. A dose of from 3 to 4 centigrammes (½ to ¾ grain), associated with 1 centigramme (⅙ grain) of morphine, was injected hypodermically fifteen minutes before the administration of chloroform in various long surgical operations like laparotomy, hernia, etc. In one hundred and twenty observations made, the heart continued to act strongly and in a perfectly regular manner during the chloroform narcosis.—*Therapeutic Gazette.*

Diver's Palsy.—Dr. Sharples has given a clinical account of this condition and an anatomical description of the changes found in the cord of a patient. The patient was a man who had for some years intermittently followed the occupation of a diver in deep water. For two weeks before the onset of his illness he had been diving to the depth of over two hundred feet, often remaining half an hour under water. He used the ordinary diving dress and helmet. On April 26, 1893, he dived for the fifth time, and returned to the surface sooner than usual. As soon as his helmet was removed he complained of sharp pains in his arms and legs, and almost at once became unconscious. He remained so for an hour and a half. On regaining consciousness he complained of shooting pains in his arms and fingers, which were aggravated by movement. Motor power in the arms and legs was completely abolished; sensory power was impaired in the arms and absent in the legs. The sensory impairment extended as high as the neck. The bladder and rectum were both paralyzed. In about two weeks mucous râles were audible in the chest on both sides, and there was dulness over the bases of the lungs. Bedsores also began to form, cystitis was now present, and the rectum remained paralyzed. No knee-jerk was found on either side. The condition of the patient gradually became worse and the paralysis did not improve. He finally died with a high temperature, the result, doubtless, of septic absorption from his extensive bedsores. The necropsy was made thirty-six hours after death, and the cord was found to be very soft and in parts almost diffluent. After hardening and staining, changes were found, chiefly in the cervical and dorsal regions, the lumbar region being apparently normal; they consisted of softening in the posterior column and also in the lateral. Similar changes were found in the dorsal region, but were much less extensive. The conditions found were apparently the result of softening and inflammatory changes, presumably secondary to hemorrhage occurring at the time of onset; but it certainly is curious that no definite trace of such hemorrhage was found, and especially that there should have been no change in the lumbar region with such paralytic symptoms as were present.

Dysphemia.—This is the name proposed for stammering by Dr. C. F. Coxwell in the *Intercolonial Quarterly Journal of Medicine and Surgery*. The author points out that stammering is the result of some interference with the oral or laryngeal mechanism of speech and a consequent want of correspondence between them. He regards it as largely a spasmodic affection, the result of inhibition, which leaves the liberating element temporarily unopposed, and so gives rise to spasm. On the other hand, inhibition of the liberating element may cause temporary paralysis. In the next few pages are embodied a description of the relation of the related cerebral centres—speech and auditory—and an account of the gradual development of their functions. He next proceeds to discuss the theoretical question of local control over discharge of energy in nerve-centres, and considers the question of the existence of a general inhibitory centre and the nature of neuroses generally. Dysphemia is then considered with reference to these theoretical considerations, and an explanation offered of its phenomena. In conclusion, there is a succinct and practical account of the various measures necessary for its successful treatment.

Argon.—A communication to the Royal Society, London, Eng., by Lord Rayleigh, formerly professor of physics at Cambridge, and Professor Ramsey, who holds the chair of chemistry in the University College, London, gives certain definite information concerning the new element in the atmosphere which they have discovered. A few years ago, Lord Rayleigh found that nitrogen obtained from air is heavier than that obtained from chemical substances. This led to a series of patient experiments and the final isolation of a hitherto unrecognized constituent of air, which has been named argon, from two Greek words signifying "no work." Its name explains its position, which is one of inactivity. To Professor Ira Remsen, proof-sheets of these communications were forwarded and became the subject of a talk at the Johns Hopkins University, which was listened to by professors, students, and others interested in science. Taking the sum total of evidence into consideration, Crookes's conclusions in regard to its spectroscopic analysis and Olszewski's experiments in liquefaction, Professor Remsen affirms that the balance of evidence seems to point to the conclusion that argon is an element.

MEDICAL RECORD:

New York, March 16, 1895.

INSTRUCTION IN MILITARY MEDICINE.

THE experience of the Civil War demonstrated the necessity of a general dissemination of a knowledge of military matters among the people. Our standing army is, and always will be, a small one, and the safety of the country in the case of war, which is always a possible event that must be provided for, will lie in the large body of young men who have received at least the rudiments of a military education in the schools, or who have had a practical training in the National Guard. There is still, however, one department, and a most essential one, which has been overlooked in this scheme of national defence, namely, the medical department. The medical staff of the army, especially since it has been reduced by a penny-wise Congress, is insufficient for the needs of the service even in times of peace, and in case of war its ranks would have to be drawn from practitioners in civil life. But every one who has any conception of the many peculiar duties of the army surgeon knows that no physician in civil life is fully equipped to perform those of a military medical officer.

In a lecture delivered last autumn at the Harvard Medical School, Dr. John Van R. Hoff, of the United States Army, dwells upon the duties of the military surgeon, and shows how necessary to their intelligent performance is a special training. This training, he contends, should be given in the medical schools, and he appeals to the faculties to introduce into the curricula of the schools a systematic course in military sanitation. He holds that war sooner or later is inevitable, and that it is the part of patriotism to be ready for it when it comes.

There can be no doubt of the desirability of having a reserve force of military medical officers scattered throughout the country, but we question the advisability of adding to the already exhausting labors of our students. The standard of medical education is being constantly raised, and each year new subjects of great importance, if not of absolute necessity, to the future physician are being added to the curriculum, and until the term of study is greatly lengthened there will be little time for instruction in details of military practice, which in all probability the physician would never be called upon to undertake. We already have a sort of training-school in the medical department of the National Guard, and now that a national association has been formed, this service will doubtless become more and more attractive to young medical men in the larger cities of the country. Later, when more time is given to medical education, courses in military sanitation, in the duties of national, State, and municipal health officers, and in other subjects bearing directly upon the daily work of the practising physician may profitably be added to the curricula of our medical schools. And even now it might be possible to carry out Dr. Hoff's suggestion in some of the larger and richer schools, adding the course as an elective study perhaps, and not at first making it obligatory upon all.

HOME FOR THE DYING.

A WRITER in the *Evening Post* urges some philanthropic person to "earn the great reward" by establishing in this city what we might term a dying-in hospital. Such an institution, it is stated, was founded in London four years ago, and provides ten beds for those pronounced to be in a dying condition or beyond hope of recovery. While we have nothing strictly corresponding to this charity here, we are not lacking in homes for incurables and for the aged.

Those for whom science can offer nothing, are not the ones sought for by hospital physicians, and even in the institutions for incurables many are admitted who prove quite capable of being restored to usefulness.

There is always room for good to be accomplished in a large city like New York, and the idea may strike some one favorably. It is unquestionably often a great hardship to a poor family to minister during the last days to a member slowly sinking under the inroads of cancer or phthisis; and surely no institution at the present time cares to receive such cases when they have passed a certain point.

THE STATE AND THE DRUG-STORE.

A LEGISLATIVE investigation of the State Health Board brings out the fact that very little work is being done in the matter of drug adulterations because of want of money. Dr. W. G. Tucker, Director of the Laboratory, stated that a collector was sent out over a route through the State. He buys drugs, which are sent to Albany and there tested. Last year sixty-three different localities, representing many hundred stores, were visited, and drugs or samples taken. Where impure drugs are found notices are sent to the dealers. The places are not, however, visited again to see if the quality is improved. Dr. Tucker said that, as a rule, only such drugs as were easily adulterated, or apt to be too weak or strong, were, as a rule, taken. In the majority of cases examined last year the drugs were impure. He thought that if they proceeded against some of these dealers it might remedy this condition, but this would not be popular in this country.

Dr. Tucker presents a very extraordinary state of affairs if his remarks are properly reported. The State sends out a collector on a junketing tour through the state. Samples are bought and tested, and usually found defective. This ends the matter. There is no punishment threatened or inflicted, and the Director

thinks that punishment "would not be popular in this country!" We very much doubt if the people of the State are such fools as the Director thinks. No one cares to be cheated by his druggist any more than by his grocer, and it may at times prove a very serious matter.

There is no particular need of the State poking itself into drug-stores anyway. Good and bad druggists are generally distinguishable, and the matter adjusts itself. If, however, the State is to investigate adulterations in drugs, it should do it in an efficient manner. The present work and methods are farcical.

POLITICS AND THE EPILEPTIC COLONY.

We have always felt the utmost sympathy with the scheme for establishing a colony for epileptics. But we have been sceptical regarding the propriety and wisdom of making it a State affair.

We find that our apprehensions were well grounded. The *Sun* appears recently with an editorial protesting against a proposed bill which has been introduced into the Legislature and which provides for a reorganization of the Craig Colony. It intimates that this reorganization is for "spoils," and that it will turn the Colony into a political machine. We do not know why the *Sun* complains. The Epileptic Colony is "spoils;" the Republicans are victors and to them the "spoils" belong, according to the politician's doctrine. We trust, however, that in this case a scheme that promises so much good will not be frustrated by the spoilsmen.

THE MEDICAL POLITICIAN AND THE PROPOSED NATIONAL BOARD OF HEALTH.

The Philadelphia *Polyclinic* is pessimistic and cautious in the following terms: "The medical politician," it says, "is one of the worst of his class; clothed in the gown of a learned profession, his true character is the more readily concealed and his opportunities for evil are thereby multiplied. That such men exist is a sad but indisputable fact, and it is well known that they are actively at work in the hope that some of the loaves and fishes to be distributed by the new department, or some of its opportunities for personal aggrandizement of a less material character, will fall to their lot.

"It, therefore, becomes the duty of those interested in the health of the community, and in the purity of government, not less than in the elevation of the medical profession, to be on their guard and to see to it that while they assist all proper efforts to concentrate and improve the administration of health affairs in the United States, the fruit of their toil shall not be plucked by self-seeking politicians with a medical degree."

We do not entirely agree with the low estimate of medical politicians put forth by our contemporary. The medical man has as yet had little chance in politics, but he has not abused it to any such extent as has been done by others. The medical men in our State Legislatures have proved themselves efficient and useful as a rule. The medical men who have held positions on Boards of Health, as coroners and as city officials, have not been among the worst but among the best of their class. This is particularly true as regards sanitary work, which has called into prominence some of the best talent in the profession.

We trust and believe that the stigma cast upon the medical man in politics is becoming constantly less deserved. Every medical man should take his share of political work, and with the increasing importance of public medicine this share is becoming of the profoundest importance.

THE INCREASE OF NERVOUSNESS.

The feverish activity of the present age, Professor Erb, in his Heidelberg address, seems disposed in great measure to regard as a symptom of disease. Our century began in disorder and commotion; restlessness, ease of communication, velocity, have practically annihilated time and space. Rushing from change to change seems the only alternative to work. Overcrowding, over-work, over-stimulation, increased use of tobacco and alcohol, railway travel with its nerve-jarring motion, all tend to loss of nerve tone. This rapid, restless, movement has left an irritable and slow recovering nervous system, the neurasthenic, a refined expression of hysteria and hypochondriasis. Its essentials are increased sensitiveness, with weakness, weariness, lack of power of endurance, and defective recuperative power.

Thus far the *British Medical Journal* agrees with the learned German. This is all true; but there is another side to the picture. There is some slight increase of nervousness, but there is also a much greater knowledge of the subject, a greater tendency to freedom of exercise, to freedom from too strict conventionality, to the freedom from ailments that comes from healthful surroundings. There is a decrease in conventional religious feeling and its allied emotional excitement. Worry, not over-work, is the danger of the age. "And this danger," says the *British Medical Journal*, "arises from decreasing and deferred marriage. . . . No one is made good by acts of Parliament, nor is there any very serious risk to the stability of society in the so-called development of neurasthenia."

Original Work in Connection with a Public City Hospital.—The Cook County commissioners propose to establish a laboratory at the hospital for the following purposes: Original research and experimental work; bacteriological and chemical experiments prosecuted by means of the best instruments and apparatus obtainable; the organization of a clinic under the direction of an eminent physician, with ten assistants, to make complete scientific examinations, including a study of all the secretions of the human body; the production of immunes, under which general term are listed all the recently discovered antitoxins, nucleins, serums, vaccine, and lymphs, and to which will be added the new discoveries expected to be made; scientific examinations of milk and milk products, and other food used at the county institutions. A beginning was made last year by a small appropriation. Dr. A. Gehrmann is the bacteriologist, and Dr. John A. Wesner is the chemist.

News of the Week.

Professor Dujardin-Beaumetz died at his home in Paris, on February 16th. He had been ill for about two weeks, but a fatal termination was not anticipated by his friends. He was a Commander of the Legion of Honor, member of the Conseil d'Hygiène et de Salubrité, attending physician to the Hôpital Cochin, and editor of the *Bulletin de Thérapeutique*. He was a most prolific writer, chiefly on therapeutic subjects, and, unlike many who write much, he also wrote well. His last literary work was the preparation of an article on the "Diseases of the Muscles," for the "Twentieth Century Practice of Medicine," now in course of publication in this city, an article which was completed but a few days before his untimely death.

Dr. Daniel Hack Tuke died on March 6th, in London, aged sixty-eight. He was born in York. His predilection for psychological medicine was in a sense hereditary, his great-grandfather, William Tuke, having founded the York Retreat for the Insane, in 1793. He was the author of a large number of works and minor articles on mental disease, and was the editor of the "Dictionary of Insanity" which bears his name.

Resignation of a Hospital Staff.—The entire attending and consulting staff of the Ottawa General Hospital has resigned in consequence of a disagreement with the lay board of directors. At the last meeting of the directors it was voted that the appointments on the medical staff should not be permanent, but should be for a period of three years only, the directors having the right to refuse a re-election to any member of the staff whom they, for any reason, might not care to reappoint..

Treatment of Influenza.—Plicque (*Presse Médicale*, February 6, 1895) adheres to the division of the various forms into thoracic, nervous, gastro-intestinal, and cardiac, but points out that it is not rare for the different forms to be combined together or to follow one another. Treatment should first be prophylactic. When several in one family are attacked, they should be isolated in separate rooms, since when together they appear to infect each other. In common cases without special complications the patient should keep his bed for two or three days, and keep to his room for eight days; otherwise relapses and nervous complications are liable to arise. The medicines recommended by Plicque are antipyrin 30 to 60 grains, tincture of aconite 10 to 30 drops per diem, quinine, and coffee. Antiseptic treatment to the nose, mouth, and pharynx is important—boracic-acid gargle, boracic vaseline to the nasal cavities, and great care of the mouth. This treatment does much to avoid complications and perhaps broncho-pneumonia. For the spasmodic cough in thoracic complications he recommends: Tinct. belladonna, tinct. aconiti, tinct. droseræ of each 30 minims, tinct. myrrhæ ʒ ijss.; 20 to 30 minims per diem. Congestion of the bases of the lungs may be relieved by dry cupping; blisters should be avoided. In respiratory catarrh emetics are useful in children and adolescents, and chlorhydrate of ammonia. Nervous complications with excitement and delirium are best treated with bromide of potassium, 30 to 60 grains per diem. For nervous depression he recommends equal parts of tincture of kola and coca. For the cardiac form Plicque advises dry cupping, sinapisms, subcutaneous injections of caffein and ether or of camphorated oil (sterilized olive oil ʒ ijss., camphor 30 grains). In the gastro-intestinal form emetics are good in young subjects at the onset, and saline purgatives; if much diarrhœa, intestinal antiseptics (salol, naphthol, and salicylate of bismuth). During convalescence high altitudes are better than sea-air.

Masonry and the Medical Profession.—Dr. Thomas R. Evans, of Mt. Carbon, West Va., writes: "I waited to see if some jealous mason would notice a sentence in your otherwise very pleasing mention of masonry in the MEDICAL RECORD of February 23d. But modesty, or the dislike to answer the *ex-cathedra*, especially as it is the arbiter and 'morgan' of so many original articles, or from the fact that true masonry never vaunts itself, there has been no reply. Unless this notice has been anticipated and is awaiting its turn to see the light, masonry in the South has always 'taken a marked hold upon the profession,' and in the North and West the same is probably true."

Permanganate Treatment of Morphinism.—Dr. W. Moor writes that he has observed only twenty-one cases instead of seventy-one, as stated.

Tri-State Medical Society of Iowa, Illinois, and Missouri.—The next meeting will be held in St. Louis, April 2, 3, and 4, 1895.

The New York Medico-Surgical Society was organized March 4, 1895. The objects of the New York Medico-Surgical Society are the discussion of medical and surgical topics and the cultivation of social intercourse among its members. Meetings are held on the first Monday of every month, except July, August, and September. Membership is limited to one hundred. No initiation fee—annual dues, $3. Edward J. Bermingham, M.D., is President, and Samuel E. Milliken, M.D., Secretary.

Physical Examination by Physician of Her Own Sex.—Judge Andrews has just decided that it is the absolute right of the plaintiff to have any physical examination required by law. The examination made by a physician of her own sex, to be designated by the court or the judge.

Danger to the Craig Colony.—A bill has been introduced into the Legislature by Mr. Kelsey, of Livingston County, to remove the five managers of the Craig Epileptic Colony, and make places for twelve managers selected on another plan. This scheme is described by the Rochester *Union and Advertiser* as a "disreputable scheme for looting that institution." The *Post-Express*, also of Rochester, opposes with equal intelligence and conviction the Kelsey bill.

The Regulation of Chiropody.—A bill has been introduced into the State Legislature which proposes to incorporate a "Pedic Society," and through its agency to regulate the practice of chiropody. The bill provides that persons who wish to engage in chiropody in the

future must pass an examination, to be conducted by a Board of Examiners of the Pedic Society, upon the anatomy and physiology of the feet, therapeutics, chemistry, minor surgery, and bandaging. Each applicant must pay $10 to the Board as an examination fee, in advance, and $25 to the Pedic Society if he receives a certificate of qualification. Finally, the act makes it a misdemeanor to practise chiropody without conforming to its requirements.

The German Medical Congress.—The value of antitoxin serum in the treatment of diphtheria is one of the principal subjects set down for discussion at the German Medical Congress to be held at Munich from April 2d to April 5th. The subject will be introduced by Professor Heubner, of Berlin, and Professor A. Baginsky, of Berlin, will read a paper on the subsidiary effects of the serum. The other subjects selected for special discussion are the therapeutics of iron, to be introduced by Professors Quincke, of Kiel, and Bunge, of Basel; and the pathology and treatment of typhlitis, to be introduced by Professors Sahli, of Bern, and Helferich, of Greifswalde. An exhibition of apparatus, instruments, and preparations will be held during the Congress.

Dr. Arnold Hallett died in Norwich, Conn., March 9th, aged sixty-nine. For thirty years he was a physician in Brooklyn, being connected with the Long Island Hospital. He was born in St. John, N. B., and graduated from the College of Physicians and Surgeons, New York. He was a member of St. Peter's Church, Brooklyn.

A Medical Building.—A project is on foot to erect a ten-story office building in Chicago, to be known as "The Medical." The intention is to have the building given over to doctors for offices, and the rooms and conveniences are to be arranged with that object in view.

Small-pox at Hot Springs, Ark.—An epidemic of small-pox has broken out at Hot Springs, Ark. Forty-two cases are reported to have occurred. A house-to-house vaccination is being made, and other precautionary measures taken. The authorities report that they expect to have the epidemic under control within a short period.

Dr. Jenkins Appointed Special Pathologist.—At a meeting of the Board of Coroners, held March 2d, Dr. William T. Jenkins, recently Health Officer of the Port, was appointed special pathologist to the board, without salary. His duties will be to assist in making autopsies when requested, and it is stated that Dr. Jenkins had offered his services gratis.

Death of Dr. F. N. Taliaferro.—Dr. F. N. Taliaferro, formerly of Hicksville, L. I., died of tuberculosis, January 16th, at Aiken, S. C., whither he had gone to regain his health. With bright prospects he was untimely cut-off at the early age of thirty-three.

New York College of Pharmacy.—Senator Cantor's bill authorizing the New York College of Pharmacy to confer the degree of Doctor of Pharmacy and to increase its holdings to one million, has passed the Senate.

Antitoxin and the Health Board.—Dr. Hermann M. Biggs, director of the Bacteriological Department, reports that the general mortality from diphtheria in New York has been reduced nearly forty per cent., a result apparently due to the use of antitoxin.

Correction.—By a typographical error in Dr. Eshner's article, the dose of pilocarpine prescribed is given on page 302 of the MEDICAL RECORD for March 9th as grain $\frac{1}{2}$, instead of grain $\frac{1}{15}$.

Obituary.

MATTHEW D. FIELD, M.D.,

NEW YORK.

DR. MATTHEW D. FIELD, a well-known medico-legal expert, and surgeon to the Manhattan Elevated Railroad, died on March 6th, of heart disease, after an illness of four months. Dr. Field was the son of Matthew D. Field, and nephew of the late Cyrus W. Field. He was born at Nashville, Tenn., forty-one years ago. In 1875 he was graduated from Williams College and finished his education at Bellevue Hospital, receiving his degree of M.D. in 1880. Dr. Field was an examiner in lunacy for the city, and also, from the opening of the elevated railroads, surgeon of the system and the right-hand man of Colonel Hain. Dr. Field was a member of the Medico-Legal Society, of the New York Medical Society, and of the Democratic Club. Dr. Field contributed a number of important articles on medico-legal subjects. He is survived by Mrs. Field, who was Miss Atwater, and their two children. His three brothers are Captain Wells L. Field, Commander of the school-ship St. Mary's; Henry M. Field, of Brownsville, Tex.; and Heman L. Field, who is also in the Southwest. The funeral took place at the Field residence, and the burial will be at Stockbridge, Mass., on Monday.

Reviews and Notices.

DOSE-BOOK AND MANUAL OF PRESCRIPTION WRITING. By E. Q. THORNTON, M.D., Ph.G., Demonstrator of Therapeutics, Jefferson Medical College. 12mo., pp. 334. Philadelphia: W. B. Saunders. 1895.

THIS manual covers a great deal of ground and is full of practical suggestions regarding all the departments of knowledge touched in prescription writing. There is a very complete list of the officinal drugs, in alphabetical order, also the newer remedies with their dosage, in apothecaries' and metric systems, useful points on prescription writing, a very intelligible comparison of relations of the different weights and measures. It will take its place in the front rank of works of its sort, and appealing as it does to the needs of a large class of practitioners, will doubtless command a large patronage.

THE THEORY AND PRACTICE OF MEDICINE. By FREDERICK T. ROBERTS, M.D., B.Sc., F.R.C.P.; Professor of Materia Medica and Clinical Medicine at University College, London. Ninth Edition. 8vo, pp. 1168. Philadelphia: P. Blackiston, Son & Co. 1894.

THE ninth edition of this valuable work bears evidence of very careful revision and much judicious elaboration. True to the requirements of the times, the painstaking author has paid special attention to the relations of bacteriology to disease, and has prepared new sections dealing with the general therapeutics of the principal systems and organs as a preliminary intro-

duction to the study of the symptoms and diseases belonging to each. The rapid advances made along different lines have been carefully noted, but even the time taken to get a work of this size through the press leaves some important recent topics necessarily unnoticed. No opportunity has been offered for reference to the important subject of the serum-therapy of diphtheria, as investigations bearing thereon have been elaborated since the work went to press. But this circumstance will not materially detract from the value of the work nor in any direct way interfere with its continued popularity as a leading authority in general medicine.

The Life and Letters of Dr. Samuel Hahnemann. By Thomas Lindsley Bradford, M.D., author of "Homœopathic Bibliography of the United States." 8vo, pp. 513. Philadelphia: Boericke & Tafel. 1895.

This volume, giving in much detail the life, character, and letters of the founder of homœopathy, carries with it much interest in the study of the methods and indefatigable industry of one who had the courage of conviction, and who fought consistently for the establishment of what he considered a leading principle.

Clinical Lectures and Essays on Rickets, Tuberculosis, Abdominal Tumors, and Other Subjects. By Sir William Jenner, Bart., K.C.B., M.D. London, etc. 8vo, pp. 329. New York: Macmillan & Co. 1895.

Rarely are collected in a single volume of small size so much of valuable clinical material as can be found herein. The ripe experience, broad views, and soundness of judgment of the author are manifest in a striking degree, and make the subject not only interesting but instructive. The commendable endeavor to make all the varied pathological conditions present in these common and wide-spread diseases, accord with the well-recognized symptoms so often presented, rounds out the subjects with a completeness of description and practical interest which cannot fail to give new points of view to every reader, and new ideas to every student.

A Monograph on Diseases of the Breast. Their Pathology and Treatment, with Special Reference to Cancer. By W. Roger Williams, F.R.C.S., Surgeon Western General Dispensary. 8vo, pp. 572. London: John Bale & Sons. 1894.

The previous writings of Mr. Williams on the "Principles of Cancer and Tumor Formation" naturally prepared the way for the present elaborate work on "Diseases of the Breast," with which, unfortunately, malignant trouble is most frequently associated. With a thoroughness which could be anticipated the author has gone over the entire ground indicated by the title. Beginning at the ontogeny and phylogeny of the gland, he discusses in turn its morphology, secretory anomalies, variations *per defectum et erraticum*, its histology, the varieties of mammary neoplasms and their relative frequency, and then proceeds to the interesting question of the pathogeny of cancer and other neoplasms, and to the attendant discussion of the microbe theory. In common with the majority of leading pathologists the author adopts the cellular and embryonal theory as against the microbic, maintaining that the microbe has not been found because there is none. The chapter on "Morphology" is specially interesting and is treated in a satisfactory and exhaustive manner. The general pathology of cancer, the clinical features of the disease, and the treatment are also very fully considered, and elaborate statistics are furnished to establish the benefit of operative procedure. Differential diagnosis is viewed principally from the clinical stand-point, and the leading features of benign tumors are fully set forth in the different chapters concluding the work. As a whole the work is a great success, being the most elaborate and scholarly treatise on this subject that has as yet appeared.

Notes on the Newer Remedies: Their Therapeutic Applications and Modes of Administration. By David Cerna, M.D., Ph.D., Demonstrator of Physiology and Lecturer on the History of Medicine in the Medical Department of the University of Texas, etc. Pp. 253. Second Edition. Philadelphia: W. B. Saunders. 1895.

This little book presents a large amount of information, collected from various sources, and arrayed in alphabetical order, concerning the newer and mostly unofficinal materia medica. While nearly all of the contents of the book should be familiar to the diligent reader of current medical literature, the author has rendered a service to the profession in bringing together in one volume the facts concerning the newer remedies. We believe, however, the official preparations, acetanilid, codeine, hamamelis, hydrastinine, hydrogen peroxide, lanolin, menthol, naphthalin, naphtol, nitroglycerine, paraldehyde, phytolacca, picrotoxin, quebracho, resorcin, rhus, sparteine, strontium bromide and lactate, terebene, terpine, thymol, and viburnum are sufficiently well presented in the usual text-books upon materia medica. In a work which is a compilation errors are not easily avoided, yet the dose of creosotal (creosote carbonate) is not seven and a half to fifteen drachms, and if it were, the equivalents are not ten to twenty grammes. Other statements are incomplete; for instance, this drug is said to be soluble in alcohol; as a matter of fact it will take up less than fifteen per cent. Occasionally we find omissions; certainly strontium iodide is quite as deserving of mention as is the bromide and lactate. Some definitions do not define: for example, it is questionable, to say the least, if morrhuol is the active principle of cod-liver oil, and that it has the same uses as the oil. Usually the pharmacopœial nomenclature is followed, but among the exceptions we would note naphthalin and naphthol. The subjects are in general presented with sufficient fulness, but in several instances the contained information is incomplete and unsatisfactory. This is the more to be deprecated in a work dealing with subjects not usually fully treated of in the text-books. This edition is an improvement upon the first, but it leaves much to be done in the way of editing and comparing the ever-increasing information to be found in the journals.

Bulletin of the Harvard Medical Alumni Association. Number 7. Report of the Fourth Annual Meeting, held in Boston, June 26, 1894. Published by the Association.

This "Bulletin" contains an address by the President; a Report on the Condition of the Medical School; addresses by Drs. W. W. Keen, William Osler, William M. Polk, John I. Billings, and the President-elect, Dr. George B. Shattuck, which are all good.

The Medical School, as well as the Alumni Association, is shown to be in a very flourishing condition.

Chemistry: General, Medical, and Pharmaceutical, Including the Chemistry of the United States Pharmacopœia. A Manual on the General Principles of the Science and their Applications in Medicine and Pharmacy. By John Attfield, F.R.S., Professor of Practical Chemistry to the Pharmaceutical Society of Great Britain, etc. Fourteenth Edition. Philadelphia: Lea Brothers & Co. 1894.

The fourteenth edition of any scientific work speaks for itself, and is the most striking possible statement of its real value. Add to it the fact that the author was awarded a gold medal in 1883 by the First International Pharmaceutical Exhibition, held in Vienna, and the uncertain purchaser need hesitate no longer in selecting a standard work on chemistry.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 25, 1895.

EGBERT H. GRANDIN, M.D., PRESIDENT, IN THE CHAIR.

The Diagnosis of Cutaneous Syphilis, Illustrated by Lantern Slides of Syphilis and other Skin Diseases.—DR. GEORGE H. FOX made the demonstration. He first showed a few cases of extra-genital chancre. One was upon the lip, a common site; another upon the chin, a rather unusual site. Next came early exanthema, or skin lesions during the first year, consisting usually of papular or macular, or maculo-papular eruptions. The early syphilide was symmetrical and disseminated; in some cases it was abundant, in others not abundant. The further removed they were from the date of the infection the more likely were the cutaneous lesions of syphilis to be located upon more limited portions of the body and to affect deeper tissues. The old iron-bound division of syphilis into secondary and tertiary was being given up to-day, because some of the tertiary lesions would occur in the early course of the disease, while some of the so-called secondary lesions might appear fifteen or twenty years after the infection. Nor would he speak of the division usually adopted, the macular, papular, vesicular, and pustular eruptions of the early stage. The vesicular eruption was rarely if ever seen. The usual form was the papular, although a number of the slides exhibited the macular or mixed forms. The papules were usually miliary or lenticular, or were large and of circular form. The lesions felt like small lumps in the skin, and projected to a varying distance above it. The peculiar purple color, which was of aid in diagnosis, could not be shown in the photos presented.

A case of lichen planus was shown which might have been mistaken for syphilis, but there was seldom much resemblance between the two. A case of syphilis bearing some resemblance to psoriasis followed. The lesions having in this case a tendency to become large, the larger ones healing in the centre, producing an annular form. Next was a case of variola which looked like a papular syphilide, the distribution also being the same. Dr. Fox had seen a number of cases of variola at Willard Parker Hospital in which the diagnosis from syphilis would have been very difficult from the appearance of the lesion alone. Next was a case of papular or seborrhœal eczema, but the lesions were not rounded as in syphilis, and they showed a tendency to spread or form a diffuse inflammation of the skin, patches running together, and usually being scaly. Next was a case of chronic acne of the back, presenting little basis for error in diagnosis. A case of general eruption followed, with long scratches which in themselves pointed to pediculosis, for there was no other disease, not excepting scabies, in which there was more violent itching, with a tendency not only to scratch, but even to tear, the skin. A case was then shown of large papular syphilide of the forehead and about the mouth, and another of macular syphilide of the forehead, described as the corona by older writers. The large papular syphilides were apt to become moist upon the surface, and the outer layer being removed, leave superficial ulceration. They were apt to be associated with mucous patches upon the lips and oral cavity.

A case of ringworm was shown, resembling papular syphilide, with tendency of the papules to flatten and form circles. In one instance the diagnosis was peculiarly difficult until it was shown, by the presence of mucous patches and by treatment, that there was both syphilis and ringworm. In one instance erythema multiforme upon the face had presented some resemblance to syphilis. In the case of a woman who had very striking Hutchinsonian teeth, pointing to hereditary syphilis, there was a distinct eruption of recent syphilis, showing that this form of teeth did not always indicate hereditary syphilis or that subsequent infection could take place. Dr. Fox thought either explanation might be correct.

Perhaps the majority of syphilitic patients had no lesion upon the palms, yet in many, one could make the diagnosis by the lesion in this location alone. It was apt to appear considerably later than the early lesion upon the body and extremities. The same fact occurred in variola, and patients could be seen in small-pox hospitals digging out the eruptions on the hands with the penknife after the eruption had disappeared from other portions of the body. In many cases in was difficult to distinguish by the eruption upon the palm or sole alone, whether it was a case of syphilis or of eczema, but it was very apt to be one of the two, where the rest of the body was free, and not psoriasis or other affection. In the majority of cases of syphilitic skin eruption it was unnecessary to ask the patient his history; syphilis was written upon the skin, and it ought not to be mistaken for anything else by one who had had any experience.

He then passed to tubercular syphilis, and explained that the term was used simply in relation to the nodular appearance of the lesion, and not to any tuberculous infection. Usually this form of eruption came late, or in the third stage. It was shown in comparison with eczema, with tubercular leprosy of the face, with psoriasis, etc. In psoriasis the infiltration of the skin was slight and the scaling was marked. Lupus vulgaris of the face was sometimes mistaken for late syphilis, but it often gave a history of existing for years, which was not true of active syphilitic lesion; and the latter disease had not the same tendency to remain in one spot. In this connection he showed cases of fungoid or vegetating condition of the syphilitic nose and face, and one of early extensive destruction of the middle face. The general practitioner was liable to change his diagnosis in a case of syphilis if it failed to respond to medicinal treatment in a short time, and for that reason patients often suffered from advancing lesions which could be readily controlled by first instituting general hygienic treatment, giving proper food and exercise in the air, then resorting to iodide and mercury, when a change for the better would become quickly apparent.

Prescribing Druggists.—DR. JOHN A. IRWIN called attention to the well-known fact that all druggists in the city, with possibly half a dozen exceptions, prescribed over the counter. Any person asking them for something to relieve headache, or other ailment, but not specifying any medicine in particular, would be given some remedy supposed to be appropriate to the case. This was a violation of the law regulating the practice of medicine, and worked harm not alone to the medical profession, but especially to the public. He thought it was a matter which should be acted upon by the Society. Individual members of the profession could not be expected to get the necessary evidence and prosecute those who thus violated the law. He moved that a committee be appointed for that purpose.

Some remarks were made by DR. W. C. PHILLIPS, the President, and others, mostly in explanation of the machinery now in existence for this purpose, and on motion of Dr. Phillips an amendment to the original motion was passed, directing the comitia minora to have evidence obtained through the counsel against druggists who prescribed illegally over the counter, and to prosecute them.

The Plague is reported to have broken out at Amoy, China, where the average number of deaths is fifteen daily.

Clinical Department.

APPENDICITIS DURING PREGNANCY.

By N. B. BAYLEY, M.D.,

HAVERSTRAW, N. Y.

In the MEDICAL RECORD for December 1, 1894, is an article by Dr. Paul F. Mundé on the premature delivery of a dead child induced by an acute appendicitis, in which he speaks of the rarity of appendicular inflammations during the pregnant period.

In the following case which I am about to report, the woman was a healthy one; she had never suffered from any abdominal or pelvic inflammatory trouble previous to this acute appendicitis.

On November 8, 1893, I was called to see Mrs. C. E. S——, American, thirty years of age, III-para, and then in her sixth month of pregnancy. She had a sharp intestinal colic attack in which the pain was chiefly complained of in the right side, some looseness of the bowels, with a tendency to vomiting. There was a history of indigestion and overwork, which seemed plausible causes for the attack. The usual remedies were prescribed, which gave some relief for a couple of days—so much that the patient did not send for me until the 11th, when there was a recurrence and reinforcement of all the previous symptoms. The pain was now almost entirely confined to the right half of the abdomen, quite severe, with a tendency to nausea and vomiting, occasionally. There was rigidity of the muscular walls over the right iliac region; the McBurney point being well marked upon pressure with the tips of the fingers, so much that the patient cried out with pain. My diagnosis was acute appendicitis; but as I had never seen or remembered reading of a pregnant woman suffering from this condition, there was anxiety as to its outcome. What would be the effect of these inflammatory foci in so close proximity to the fœtus, with their disturbing effect upon the whole system, and whether the case would do better with or without an operation, were questions which data were not at hand to answer.

The pain was severe enough to require opiates. I administered at first morphine, one-sixth of a grain hypodermatically, followed by phenacetin in five-grain doses every three hours, also trituration of calomel in four-grain doses every three hours. As the phenacetin was powerless to relieve the pain, opium in grain doses was substituted, and repeated sufficiently often to produce a quieting effect, but not to narcotism. This required one grain once in three or four hours on the average, for two days, when the intervals between doses were increased. The calomel was continued until some soreness of the gums, with sticky saliva, was produced, when it was omitted and potassium chlorate was substituted for a mouth-wash and gargle. The calomel, with the aid of occasional drachm doses of Rochelle salts, produced daily an easy movement of the bowels and contributed to the patient's comfort by the relief of gaseous distention. To the external surface of the abdomen hot applications with turpentine were used in this case, although the writer's preference is for the ice-bag.

The temperature rose from 101° F. on the 11th to 102° and 103° F. on the following two days; then slowly declined to normal on the 18th.

On the 14th there was a distinct, though slight, lessening of the rigidity of the muscles over the iliac region, with a decline in the temperature. The 15th and 16th were days of progressive distinct amelioration, still considerable pain persisted on movements of the body.

On the 18th the patient was fairly convalescent, with appetite returning; from this date went on to complete disappearance of all tenderness, rigidity, the McBurney point, and pain. She recovered completely, and had at the termination of the period of pregnancy a normal, though a more tedious, labor than in her previous confinements, on March 3d, and has remained well ever since.

During the attack there were at times some uterine pains, and I feared labor would be ushered in as the combined result of pain and fever, and general systemic disturbance due to the disease.

As the result of the calomel and a couple of doses of salines, the intestinal contents were kept loose with usually one, or not to exceed two, movements daily, with much relief to the tympanitic condition. This, no doubt, contributed to an aseptic condition of the canal to a slight degree. No pus was found at any time in the alvine discharges. At the time of her labor there was no thickening or induration to be made out in the region of the appendix. The puerperium was passed in a perfectly normal way.

As in this case no abdominal section was made to positively prove the diagnosis (there can be no doubt of it from the symptomatology), I had at about the same time an unmarried woman, twenty-eight years of age, pass through an almost identical attack of appendicitis, this being her second and severer attack during the year. She presented the following symptoms: Fever, rising to 103° F.; rigidity of muscles in the iliac region; slight dulness, McBurney point, pain, and somewhat tympanitic abdomen The treatment consisted of opium sufficient to dull the acuteness to pain, studiously avoiding narcotism, and the ice-bag continuously applied to the abdomen, small doses of calomel, which in this case did not act as a laxative, but was continued for its supposed antiseptic effect.

What the pathological condition of the appendicular structures was here, must be judged from the concomitant symptoms. Though both cases recovered for the present, the question whether surgical treatment would have been preferable to medicinal or palliative remedies, would most likely be decided in the affirmative for the former by a large majority of surgeons. The question of surgical treatment is one which in many cases will be decided by the environment. In a minority of cases the abdomen must be opened, and the surgeon be prepared for an emergency that may arise. This is an important question for the practitioner in districts remote from large towns, where efficient assistance or a competent surgeon cannot be easily obtained. If substantially the same proportion of cases of moderate severity of appendicitis recover under medicinal as well as surgical treatment, it will bring comfort to many practitioners and patients as well, who are situated where skilled surgical attendance is wellnigh impossible, as the practitioner has been told that no surgeon not skilled in abdominal sections should enter the abdominal cavity.

December 17, 1894.

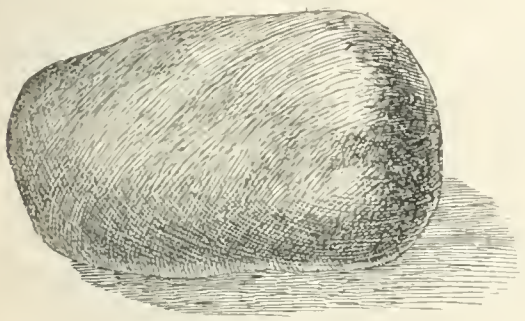
REPORT OF A CASE OF INTESTINAL OBSTRUCTION FROM A GALL-STONE—OPERATION—RECOVERY.

By D. E. WALKER, M.D.,

NEW YORK.

On December 24, 1894, I was called to see Mrs. H——, who was suffering from severe spasmodic pains in the region of the gall-bladder. She was thirty-five years of age, a rather large, active, and healthy-looking woman, whose family I had attended for some time. She had always enjoyed fairly good health, with the exception of what was called an attack of congested liver and bowels, three and a half years ago, in England. With that she had fever, and the right side along the border of the ribs was much swollen and very painful. She was then slightly jaundiced and distended, and the urine was thick and dark colored.

On the evening of December 23d, while lifting some furniture, she was seized with spasmodic pains in the region of the gall-bladder. These recurred at rather frequent intervals. She took an enema in the night and had a free evacuation. When I was called the pains continued. There was some tenderness above umbilicus, but no vomiting, no distention, no sweating, no elevation of temperature nor acceleration of the pulse, and no jaundice. The bowels, which were ordinarily pretty regular, had for a few days been constipated. At first sight the case seemed one of rather mild gall-stone colic, and I directed small doses of calomel and ipecac



Gall-stone Causing Obstruction of Intestine at Ileo-cæcal Valve. Natural Size.

with opium for relief of pain if needed, to be followed next morning with seidlitz powder and Rochelle salts. In the morning the patient took a large dose of castor-oil, which she immediately vomited and the pain increased. I saw her shortly afterward and directed a turpentine enema, without effect. I then directed a seidlitz powder every two hours till three were used, then to be followed by another enema. I had begun to fear that there was obstruction of the bowels, though the pulse and temperature remained normal and the patient had vomited but once.

Returning again about 7 P.M., on December 25th, I found the patient had taken six or seven seidlitz powders and had stercoraceous vomiting. Bowels had not moved and pulse had become more rapid, being now about 95. I decided that there was some obstruction, probably in the region of the gall-bladder, in the small intestine, and that an operation would be necessary. I had Dr. W. Gill Wylie called, and he agreed that an operation would be necessary unless relief was speedily obtained. He concluded that the obstruction was probably caused by a band of adhesions in the region of the gall-bladder—the result perhaps of some old inflammatory process; but as her general condition was good a hypodermic of morphia was given, with directions to follow it in three hours, if she did not vomit, with a large dose of compound licorice powder and a turpentine enema. At 6 A.M., December 26th, licorice was given and retained, nothing else given by mouth—nutritive enemata given during night. The turpentine enema failed. Dr. Wylie then advised the free use of Epsom salts hypodermatically, without effect.

At 3 P.M., December 26th, patient's temperature was still normal; pulse, about 100 to 105. She was etherized and Dr. Wylie, with my assistance, made an incision about an inch to the right of the median line, commencing on a line with the umbilicus and extending straight upward for about four inches. Within the cavity a mass of tough adhesions were found involving the liver, the fundus of gall-bladder, the stomach, and the intestines. It was impossible to expose to view the gall-bladder or the duodenum on account of the adhesions. There was no stone in the gall-bladder. Finding no apparent obstruction at this point, Dr. Wylie introduced his hand and feeling downward toward the pelvis, brought up what appeared to be a large cork lodged at the ileo-cæcal valve. It completely filled the intestine at that point. The large end was downward. It could be pushed upward, but not down through the valve. An opening was made in the intestine—care being taken to cut no blood-vessels—and the body, which proved to be a gall-stone, was squeezed out, sponged, and removed.

The intestine was carefully cleansed and sewed up, first with fine silk sutures, and then the peritoneal coat closed over the silk with catgut. Abdomen was closed with silk sutures, and dressed with iodoform and moist iodoform gauze. The patient made a good recovery.

The stone (see Fig.) was two inches long, and one and one-fourth inch in diameter. It was found to be composed almost entirely of cholesterine, by Professor Chandler, who very kindly examined it for me.

Dr. Russell H. Johnson, of Philadelphia, in 1885, reported a case of death from a gall-stone one and three-quarter inch in length, and one inch in diameter, lodged at the ileo-cæcal valve. The patient lived six days after initial attack. The symptoms, with exception of the spasmodic pains, were much the same. His case was not operated.

Dr. Leale reported a case, in 1879, in which invagination occurred, and the stone was finally removed by digital dilatation of the ileo-cæcal valve through the rectum, some days after initial attack.

The indications which would seem to point to a diagnosis of obstruction from gall-stones at this point are, a previous history of trouble about the gall-bladder, with a tendency to constipation, the lack of distention from gas, the slow development of alarming symptoms, and the fact that there is little tendency to vomit when the stomach is let alone.

This case emphasizes the advantage of early operation in all such cases. In this case an interesting question arises, as to the location of the stone during the three years and a half in which it must have lain quiescent in the small intestine, as I think there can be little doubt that it ulcerated through during the so-called attack of congested liver and bowels. The large end of the stone was rough and somewhat uneven, and had a little blood on it, as if it had broken loose from some attachment to the intestine. The small end was very smooth.

FILAMENTARY KERATITIS.

By A. L. MACLEISH, M.A., M.D., C.M.,

Los Angeles, Cal.

I desire to place on record an instance of this rare affection, which recently occurred in my practice in this city. Nuel and Uhthoff[1] agree in estimating its frequency at about once in six thousand cases of eye-disease. Albrand,[2] on the other hand, insists that close attention reveals a much higher proportion, 16 cases having been observed in one year in Schöler's Clinic and Dispensary in Berlin, where during the previous seven years only 8 cases had been noted. In the course of thirteen years' ophthalmic practice I have found true corneal filament, as distinguished from vitreous filament, only this once among upward of 7,000 cases of eye disease.

G. W. C——, a robust adult, had tolerated an "inflammation" of the right eye for thirty-eight days before seeking treatment, to which he was driven ultimately by dimming of vision during the last few days. I found a superficial keratitis in two foci to the outer side of the centre of the cornea, which by extension had become confluent, beginning to break down in the centre of each into shallow pulpy gray ulcers. On the lower part of the cornea, 1.5 mm. from the margin, and thus fully 3 mm. distant from the nearest border of the infiltration, there was a solitary, pellucid, knob-shaped elevation, somewhat less than 1 mm. in diameter. Next

[1] Archives d'Ophthal., xi., p. 533.
[2] Klin. Monatsbl. f. Augenheilk., 1882, S. 215.

day a smaller one was found close beside it, and on the fourth day two more close to the lower margin of the cornea, and one in the upper inner segment of the cornea, at about the same distance from the infiltrated areas. All of these were pellucid, highly refractile bodies, rising more abruptly from the cornea than vesicles do, and devoid of surrounding or underlying infiltration. On touching them with a fine probe under the corneal loupe, they were found to have the characteristic form of clavate outgrowths, freely movable on a funnel-shaped base, by which they were attached to the cornea. Lateral pressure with the probe unrolled the largest knob into the form of a filament with tiny knob-shaped end, which measured in all 2 mm. in length; under the friction of the eyelids the original apparently sessile form was again assumed. With ordinary treatment the ulcers quickly took on a healthy action, and by the sixth day were cicatrizing. The filaments persisting unchanged, were on this day removed as coherent masses by abrasion with the probe, bringing away with them small portions of the corneal epithelium surrounding their bases, from which no fluid escaped. No special application was made to these denuded areas, and they quickly healed without nebula, though one subsequently exhibited a slight wrinkling of the epithelium. There was no further formation of filaments.

First described by Leber in 1882, it is only within the last three years that these filamentary outgrowths of the corneal epithelium have attracted much notice, being specially interesting on account of their pathological uniqueness. Our knowledge of their microscopic structure is chiefly due to Hess and Nuel, whose latest investigations[1] have conclusively established that the true corneal filament is a specific structure, due to a peculiar disease of the epithelium. The epithelium in the neighborhood of the filaments is almost always found to contain large elliptical hyaline cells with subdivided nuclei. The filament springs from a funnel-shaped base consisting of this altered and proliferating epithelium. It is invariably composed of a highly twisted central cord, ending in a distal knob, this axial structure being built up of twisted, and sometimes degenerated, epithelial cells; enveloping the axis is a fine layer of hyaline material.[2]

Filamentary keratitis is found both as a primary and as a secondary affection. The primary form seems comparable to the eruption of herpes of the cornea, at least in its text-book type, for which it may readily be mistaken. Hess, indeed, holds that most of the cases classed as herpes cornea are, in reality, examples of filamentary keratitis. I have never chanced to find herpes of the cornea in the primary stage, with unruptured clear vesicles; but I should consider that the use of the probe in the manner indicated above would serve to distinguish the two affections. As a secondary effection, filaments may occur where the superficial or deeper layers of the epithelium have been injured by wound or ulcer, as, for example, when the cornea has been peppered with grains of gunpowder, or where there has been imperfect adaptation of a wound. It will be observed that in the case described above none of the filaments were within 3 mm. of the areas of the cornea affected with keratitis, and there was no evidence of local injury to the cornea; so that they would seem to be an accompaniment rather than a result of the keratitis.

According to Albrand,[3] the direct cause of the formation of filaments in suitable lesions of the cornea is the use of atropine, especially in solutions impure or not perfectly neutral. He recommends, in addition to the disuse of the atropine, the painting of the transition-folds of the conjunctiva with two per cent. solution of nitrate of silver. In the case described above, filament formation was found at the first visit, though the eye was not under the influence of a mydriatic. In many cases, as in ours, no special treatment is required beyond the abrasion of the filaments along with the affected epithelial base.

The solitary filament which is frequently found at the site of the corneal puncture, where the needle has been used for the division of "after-cataract," is, according to Hess, a pseudomorph of the true corneal filament. Its occurrence, never after discission of the lens, but only in operations for after-cataract, where the vitreous is necessarily penetrated, the absence of epithelial elements from its structure, and the fact that the corneal epithelium can be peeled off, leaving it still in situ, all go to support the old view, that this is a mere shred resulting from the protrusion of a bead of vitreous through the needle wound.

MALPOSITION OF THE TESTICLE; PHIMOSIS; ACUTE INSANITY; OPERATION; CURE.

By HOWARD CRUTCHER, M.D.,

CHICAGO, ILL.

August M——, aged thirteen, a poorly nourished Bohemian boy, was brought to my clinic by Messrs. W. B. Page and D. R. Good, medical students. Until six weeks before my examination the boy had been remarkably bright, though somewhat excitable. At the time indicated he was badly frightened by a railroad watchman, who threatened him with arrest for some trivial offence, since which date he had been violent and mild by turns, but always irresponsible in his actions and incoherent in his language. He seemed to have no conception of the purpose of the examination, but submitted quietly to my manipulations.

The first condition noted was a firmly adherent prepuce, accompanied by considerable irritation around the meatus. Further examination revealed the presence of the left testicle in the ischio-rectal space. Both conditions were congenital. The left scrotal pouch was normal to all appearances, save for the absence of its usual contents. The misplaced gland was freely movable, and the cord could be plainly outlined from the external ring downward.

It was not known that any previous attempt to transfer a misplaced testicle to its normal location had been successful, but there seemed to be no valid reason why the effort should not be made in this case. Accordingly, on January 9th, assisted by Drs. W. W. Stafford, and F. H. Lockwood, I circumcised the patient and placed the left testicle in its natural bed.

As this report covers the first successful American case, perhaps the details of the procedure may be of value for future guidance.

An incision about an inch and a half long was made in the centre of the left scrotal pouch; the testicle was then pushed upward as far as possible by an assistant, and the gland carefully exposed by dissection. The cord was next liberated well up toward the ring. Both structures were then wrapped in hot gauze and drawn away from the field of operation. The testicle was found between the superficial and the deep layers of perineal fascia, and was firmly attached to the median tendon of the perineum. The layers of fascia were then united by a double row of plain fine catgut sutures. These sutures simply united the posterior wall of the scrotal pouch, and the testicle was then placed within the scrotum, and the primary incision closed over it with a suture of fine chromic catgut. No drainage was employed. A gauze pad was adjusted snugly against the perineum and the usual dressings applied. Within twenty-four hours a decided mental improve-

ment was noted. This continued without substantial interruption until the boy was perfectly restored to his senses. It is only just to say that this happy result is wholly attributed to the beneficent influence of the circumcision. The left testicle is now securely at home in its natural resting-place, and as the union of the tissues has for some time been complete, there remains no doubt of the entire success of the operation. The boy is allowed the freedom of a well person, he is perfectly rational, but for humane reasons he has not been sent to his home, as I feared that his usual supply of substantial hospital food might not be forthcoming under the parental roof.

These cases are comparatively rare. At the time of the operation we did not know that any case had been successful; since that time two cases have been found. The first is recorded in vol. vi., p. 596, of the "International Encyclopædia of Surgery," edited by Professor John Ashhurst, Jr.,[1] and is credited to Professor Annandale.[2] In this case the patient was three years of age, the operation proving a perfect success. Drainage was employed.

The second case is reported in *The Lancet* for 1894, vol. ii., No. 2, the operation being performed by Pollard, of London, upon a child one month of age, with a perfect result. Nothing is said of drainage in this case, and the inference is that it was not employed. The results in these cases would appear to indicate that the unfavorable outcome of the operations referred to below by Mr. Curling, were due to constitutional troubles rather than to faulty technique, or to the age of the patients.

Professor Samuel D. Gross[3] mentions a few instances of the condition, but on account of the uniform failure of all operative procedures devised for its relief, he advises castration as the only rational treatment.

On page 52 of Mr. Curling's great work on "Diseases of the Testis," is found an admirable illustration of a left testicle lying in the ischio-rectal region. The left scrotal bag is absent. The same author reports some instances where the attempt has been made to transfer the testicle from its position in the perineum to the scrotum, but all the cases were unsuccessful. Mr. Curling operated upon an infant at the London Hospital, in November, 1865, and in 1871 assisted Mr. James Adams in the case of a child of eleven weeks, both cases resulting fatally. Commenting upon these cases, he says: "The results of these last two operations do not afford encouragement to a renewal of such attempts, to transfer the testicle from the perineum to its proper position at the early period of life."

In the adult the absence of the scrotal pouch precludes the possibility of success, and "on this account," says Mr. Curling, "I was led to make the attempt to transfer the testicle by operation soon after birth, before the scrotal pouch had undergone the wasting which ensues from the absence of its proper contents."

The age of my patient (thirteen years) would appear to indicate that the scrotum undergoes no degenerative changes before puberty, since the left pouch was as capacious and in all respects as normal as its opposite fellow, save only the defect already noted. It would seem, therefore, that in these cases operation might be safely postponed until shortly before puberty, without fear of scrotal wasting.

One feature of my operation has been withheld for purposes of emphasis. The author last quoted mentions the contraction of the cremaster as influencing unfavorably the result in certain cases. This suggestion led me to remove carefully all traces of the muscle, and this precaution should be an essential part of the technique of all similar procedures. It is as yet too early to predict anything touching the future of the transferred testicle, but as the gland and cord were protected from injury, there is no reason to suppose that their functions will not be carried on physiologically after puberty.

TWO CASES OF FOREIGN BODIES (PINS) FOUND IN THE APPENDIX.

BY ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO, N. Y.

OPERATIONS for appendicitis and for peri-appendical abscess have become so frequent that there is very little of special interest attaching to the ordinary case. The literature of foreign bodies in the appendix, however, is one which may certainly be enriched, and I think will be by a brief recital of the two following cases:

CASE I.—A girl, aged fifteen, in the practice of Dr. Gillette, of Cuba, N. Y., had complained for a number of months of vague and indefinite discomfort in the right iliac region. Finally, she was taken with symptoms of unmistakable acute appendicitis, and developed considerable temperature and febrile disturbance. The doctor was alert to the propriety of operation, and called me in consultation. With him I saw the case January 5th, and, in spite of falling temperature and general amelioration of symptoms, I advised operation, basing this advice mainly on a somewhat œdematous condition of the tissues in the neighborhood and rigidity of the abdominal muscles. On the following morning the operation was made with the assistance of Drs. Gillette, Allen, and Thomas, of Cuba, N. Y.; incision was made parallel to Poupart's ligament—my customary incision. Not far from the surface pus was reached, and a cavity was entered which contained three or four ounces of offensive pus. My finger in the cavity detected a sharp point, and identified it as belonging to a pin or a needle, after which without difficulty the foreign body was withdrawn by a pair of forceps and found to be a common pin. In the cavity and through the opening made the appendix itself was not seen nor found, and it seemed to me unwise to enlarge the incision or disturb tissues further to find it, it being my usual habit (to which, of course, exceptions are made), when the appendix is not found with reasonable ease, to leave it, although I know that this course is open to criticism. Nevertheless, in this instance, I contented myself with disinfecting the cavity, draining it, and partially closing the wound. Recovery was uneventful.

CASE II.—A patient, thirty-two years of age, was brought to the Buffalo General Hospital, January 25th, from Shortwell Creek, Potter County, Penn. In this case there was a history of indefinite discomfort in the right iliac region, which patient says he has noticed for at least five years. The acute attack dated back exactly one week. When brought to the hospital there were signs of extensive abscess, and the patient's general condition was bad. There was no doubt as to the presence of pus. This case was operated on immediately after his entrance by my house surgeon, Dr. Jones. In this instance the abscess cavity was widely opened; the appendix was found and tied off. In the inside of the appendix was found a fæcal concretion, three-fourths of an inch long, the diameter of a pencil. Imbedded in this by its head end was a common house-pin, whose point protruded beyond it to the distance of half an inch. The abscess in this instance had burst into the peritoneal cavity, which was washed out, and drained for forty-eight hours, after which the patient proceeded to make an uneventful recovery. This patient denies all knowledge of having ever swallowed a pin, and was as surprised as anyone at its discovery.

The coincidence of two such cases within one month seems to be noteworthy, and the cases themselves are considered of sufficient interest to justify report.

FIBRO-CYSTIC OVARIAN TUMOR—DOUBLE PEDICLE—FIBROMA OF THE UTERUS—OPERATION—RECOVERY.

By WITTER K. TINGLEY, M.D.,

SURGEON AND GYNECOLOGIST TO THE BACKUS HOSPITAL, NORWICH, CONN.

Miss KATE D——, aged thirty-five ; Ireland ; operative, thread-mill, Willimantic, Conn. ; admitted to hospital April 1, 1894. The history in brief is as follows :

Had always enjoyed fairly good health ; able to earn her living ; never had had any severe or lasting illness. Menstruation always regular, lasting five days and not attended with any pain or discomfort. About fifteen months before admission she began to have headaches, pain and discomfort after eating ; lost flesh and color. Her menstruation became very irregular and scanty. I found the abdomen very much enlarged, about the size of a woman at full term ; the growth was smooth, except at one spot just over the pubic bone, where it was distinctly nodular and uneven. Vaginal examinations revealed only the mass distending the pelvis, the uterus pushed up almost beyond reach. Fluctuation could be faintly made out both by external and internal examination. An exploring needle thrust into the growth failed to obtain any fluid. It was decided to operate, but to wait awhile, as the woman's general condition was very bad. But instead of improving the woman's condition kept getting worse, the temperature going to 103° F. each day ; pulse to 120. I determined that if anything was to be done it must be done at once, and accordingly on April 11th I operated, assisted by Drs. L. B. Almy and P. Cassidy, Dr. John Logue giving the ether. When everything was relaxed from the anæsthetic and while I was making the abdomen surgically clean, it could be seen that the tumor below was decidedly different from the main or large growth. This was shown immediately I made the exploratory incision. This incision was four inches long from the umbilicus down. The small tumor was then seen to be a fibroid of uterus, above the smooth, shining capsule of the ovarian growth. I plunged a trocar into the latter, but failed to get any fluid. The capsule was very thin and friable, tearing where the trocar entered, showing the contents to be made up of quantities of very small cysts held together by fibrin tissue.

There were two pedicles, one attached to the broad ligament and uterine tumor, the other to the pelvic wall. I tied off the latter, but finding that the one attached to the uterus was so intimately blended with the fibroid, I determined to perform hysterectomy as well as ovariotomy. The time of the operation was one hour and ten minutes.

After the operation the patient's condition was better than when she was placed upon the table. The temperature never went above 99½° F. during the entire convalescence. The pulse, immediately after the woman was placed in bed, was 120, but of fair character. The second and third days were very trying ones, the exhaustion being great, the pulse going to 160. The stump was dressed with chloride of zinc solution twice a day, and came away without any odor, and very little, if any, discharge on the seventeenth day. Patient left the hospital fat and well. The growth proved to be a fibro-cystic ovarian tumor, made up of thousands of small cysts held together by firm fibrous bands, very vascular, and forming a firm, dense net-work. I should certainly have lost the patient if I had tried to break up the cyst contents. An important point also is the woman's condition at the time of operation. It shows how often life might be saved in cases seen so late in the disease, where the general health has been so completely undermined and the conditions most unfavorable to a successful operation. Many women (in the country) are allowed to die without an attempt at an operation, simply because they will not go to a large city, and there is no one in the neighborhood that wishes to risk his surgical reputation upon them. If my patient had been sent to some distant city to a famous operator, with all the fatigues of railways, examinations, and hospital, she never would have lived to be operated upon.

GANGRENE OF FOOT—AMPUTATION BELOW THE KNEE—RECOVERY.

By WITTER K. TINGLEY, M.D.,

SURGEON AND GYNECOLOGIST TO THE BACKUS HOSPITAL, NORWICH, CONN.

MRS. P——, aged seventy-four, in poor circumstances, had undergone much privation and suffering. During the cold weather she thought she frosted the toes in the left foot. From that time she had great pain, and soon the foot from the scaphoid bone down became gangrenous. I saw her some weeks after the foot became affected. My examination revealed dry gangrene of the lower half of the foot, with the line of demarcation well defined. Although she had been refused operation by several surgeons, who declared that she never could stand the only justifiable operation, that is, amputation above the knee, I decided to give her the benefit of the doubt, and accordingly performed the operation that same afternoon, taking the leg off just below the knee, doing it very rapidly, so that she was under the anæsthetic only a short time. Everything went well, except some pain in the stump, and some little elevation of temperature, with great restlessness.

When I took down the dressings to remove the stitches, I found what had caused the pain. The anterior flap was black and moist, having a most peculiar musty odor. It certainly looked as though the disease had returned in the stump. Without any hopes of good results I ordered all the usual dressings stopped, and sterilized gauze soaked in bromine substituted, to be applied twice a day, the stump to be carefully washed at each dressing with bichloride solution one in two thousand. The result was really surprising. Gradually the black spot looked more and more healthy, the dark appearance grew less and less, healthy granulations started up, and in four or five weeks the stump was white and all healed, the anterior flap that at the time of operation was thin and flabby now being plump and firm. I think it only fair to attribute this result to the bromine, for that was the only thing applied. The woman returned to her home and six months after was perfectly well and happy. Considering her age and disease I think the result a very good one.

STRANGULATED INGUINAL HERNIA, OMENTAL—PERITONITIS.

By WITTER K. TINGLEY, M.D.,

SURGEON AND GYNECOLOGIST TO THE BACKUS HOSPITAL, NORWICH, CONN.

WILLIAM T——, aged twenty-one, lumberman, admitted to the Backus Hospital with the following history : Had always been a strong, healthy man, though the hernia had existed for several years. It was distinctly the result of lifting heavy pieces of lumber, and he never felt "safe" afterwards. Had never worn a truss, though advised to do so by his physician. Three days before admission, while lifting a log, he felt something give way in his left side and knew that his "rupture" was down. As he was in great pain, a physician was called, who made some unsuccessful attempts at reduction. I saw the man on the third day of the

strangulation, at the hospital. Found that his condition, from loss of sleep and pain, was bad. Temperature, 101½° F.; pulse, 115; small and thready; respiration rapid and shallow. An extremely tense mass completely filled the left side of the scrotum, which was swollen and painful to the touch. I made the usual incision for hernia, and found that the tumor consisted of omentum; the sac was filled with serum and blood-clots that had escaped from the ruptured blood-vessels in the omentum. The mass was as large as two fists doubled up together, and very tightly constricted at the ring. Not deeming it wise to return so damaged a piece of omentum to the abdominal cavity, I amputated it, and pushed back the stump. Considerable serum with some inflammatory products escaped from the abdomen during this part of the operation. I drained the wound with a tube, as there was considerable discharge. The patient rallied after the operation and slept most of the afternoon. Temperature at 5 P.M., 100° F.; pulse, 120. Complained of very little pain. At ten o'clock the same evening the conditions became suddenly much worse—a severe chill, followed by temperature of 105½° F., pulse 140, and respiration 35. Great pain in abdomen, and evidences of general peritonitis. I immediately ordered sulphate of magnesia in drachm doses every hour till action ensued, morphine just enough to keep down the pain, and stimulants when necessary. After sixteen drachms of the salts had been administered a very copious discharge from the bowels took place, and was followed in short order by four more. In a short time the temperature went down to 99½° F., pulse to 95, respiration to 25. Abdominal tenderness all disappeared, and the patient made a good recovery in spite of an attack of acute lobular pneumonia on the fourth day.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DEATH OF THE PRESIDENT OF THE COLLEGE OF SURGEONS, MR. J. W. HULKE, F.R.S.—HIS HUNTERIAN ORATION READ FOR HIM DURING THE FATAL ILLNESS—HIS WORK—HIS ESTIMATE OF HUNTER—HEALTH OF LONDON—SMALL-POX—INFLUENZA.

LONDON, February 23, 1895.

THE President of the Royal College of Surgeons has died during his term of office—a coincidence with the similar loss which the sister college sustained some fifteen months ago. The name of J. W. Hulke, F.R.S., was known wherever surgery is cultivated, and many who knew him well little anticipated that his career would so soon close; for, although by no means robust, he was possessed of a considerable share of health and a great amount of scientific energy and enthusiasm. He was to have delivered the Hunterian oration at the College on the 14th instant, and had fully prepared it, but when the day arrived he was on his deathbed, and his tribute to Hunter was read by Mr. Bryant. Like many who knew him, I was not aware that he was indisposed. On the 10th and 11th he was at his hospital (the Middlesex), although he had a cold and, one might say, some bronchitis. This increased, pneumonia set in, and he died on Tuesday (19th). The cold he caught was contracted during a visit to the hospital on one of the bitter nights we have lately endured, in response to a call to operate for hernia. He has thus died, so to say, in harness. Had he foreseen the event he would not have flinched, for he was always ready to sacrifice himself to duty. Mr. Hulke was an excellent president. His views were conservative and he was against the aspirations of fellows and members to share in the conduct of the college, but his stanchest opponents respected him for the straightforward and eminently fair manner in which he opposed them. Much of his work was devoted to ophthalmic surgery. He was for many years surgeon, and afterwards consulting surgeon, to Moor Fields Hospital, and contributed some of his best scientific work to this specialty, although he never relaxed his hold on general surgery. He had been president of the Ophthalmological Society, as well as of the Pathological Society. This year he was president of the Clinical Society and librarian of the Royal Medical and Chirurgical Society. He was also chairman of the laboratories committee of the conjoint colleges, and held in his time many other official positions.

Mr. Hulke was not only a skilful and learned surgeon, but made a name in other scientific work. Thus he was a naturalist of mark, and, as a result of his researches in geology, had been foreign secretary and president of the Geological Society, by which he was also awarded, in 1887, their highest distinction, the Wollaston gold medal.

It will thus be seen that Mr. Hulke was a man of broad scientific culture, and many other acquirements might be named, but it is as a surgeon that a medical journal must naturally speak of him, and as such it is not too much to say that he was universally respected, and his opinion in difficult cases most highly esteemed; while as an operator he was extremely careful and avoided all show, although his precise anatomical knowledge might have justified an attempt at brilliancy more than in the case of some well-known but rather incautious surgeons.

The meeting of the Clinical Society which was due last night was postponed until March 1st, as a mark of respect to the lamented president. At the Pathological Society the loss sustained by the death of a former president was the subject of some appropriate opening remarks. The funeral takes place to day. I had intended to send you rather a full report of Mr. Hulke's Hunterian oration, but in view of the shock caused by his untimely demise, will confine myself to a few words about it. Hunter was regarded as a biologist in the widest sense, and his work as such illustrated by examples from both the vegetable and animal kingdoms. Many of his experiments, observations, and discoveries in botany, are but little known among surgeons, but Mr. Hulke's own familiarity with this branch of study was sure not to pass by such work when reviewing the labors of the great anatomist and surgeon. Then the foremost rank among original investigators in zoology was vindicated for Hunter, by references to his researches on the "General Principles of the Blood," and those on the "Vascular System," and on "Digestion," "Absorption," and "Nutrition." Hunter's remarkable memoir on the "Life History of Bees," which is an ever-charming bit of reading, illustrates his excellence as a naturalist, and so his account of the development of the chick shows his grasp of embryology. Both these illustrations were drawn upon in the oration, and it was remarked that we find Hunter enunciating the principles of the inherent variation of species, the modifying influences of environment, the transmissibility of variations and evolution from lower to higher forms. In fact, it appears, from those of his papers which escaped destruction, that his mind was often engaged on the problems of evolution, which have in our days excited so much controversy.

Mr. Hulke's design was to present Hunter as a biologist in the widest sense of this now much used word, and for this purpose he made large use of his own words, for these, he held, best show his mind, and "the mind is the man."

The increase of deaths caused by the intensely bitter cold is not yet manifest by the returns, but will appear, no doubt, later. With the abatement in the severity which has at length come, and we may hope will stay, there seems to be a renewed prevalence of influenza.

It is perhaps doubtful whether most of the cases so named are not rather instances of sharp inflammatory cold due to exposure to atmospheric influences, and which are just as likely to pass into bronchitis and pneumonia. There is no increase of the latter, in the returns last issued.

There was only one death from small-pox last week, and that in an unvaccinated person. The fresh cases had fallen to eight in the week.

New Instruments.

A NEW AXIS-TRACTION FORCEPS.

By R. W. FISHER, M.D.,

SALT LAKE CITY, UTAH.

As the subject of axis-traction forceps seems to be attracting some attention at present, I wish to present a modification of the old Hubert forceps, which I have been using for the past two years. Dr. T. J. McGillicuddy's attachment is in the same line, and while neither he nor I can claim much originality, yet either modification is an improvement on the old Hubert. I read a paper before the Salt Lake Medical Society, November, 1893, in which I went over much the same ground as that covered by Dr. McGillicuddy before the New York Academy of Medicine, November, 1894. The difference between his and my attachment, is that he converts the forceps into a lever, while in mine it is a straight pull in the axis of the inlet.

My attachment can be applied to any forceps without any change in the construction of the instrument. It consists of a steel bar eight and one-half inches long, with a slot in one end as seen in Fig. 1.

Fig. 1.

The slot is so made that when applied it forms an angle of 85° with the forceps. It fits on just below the lock, as shown in Fig. 2. From a practical standpoint, this

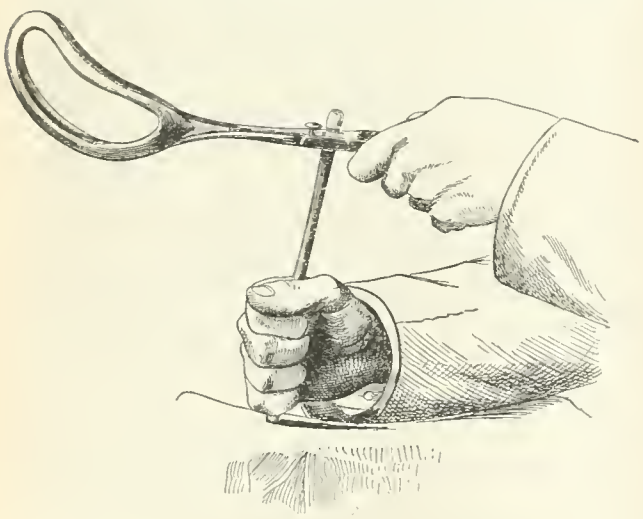

Fig. 2.

little attachment is very useful, as I know from experience in my own practice. Theoretically, it also fills the indications. Fig. 3 is used by most authors to demonstrate the planes and axes of the pelvis. If we increase the size of the diagram so that the diameters will correspond to normal in the static pelvis, measure the angles and have them mathematically correct, we will have what is supposed to represent the axis of the inlet as it occurs in the living woman. Now, if we lay the forceps on this diagram, it should give us the position in which they are when applied to the fœtal head. With my attachment, the axis of the inlet, if continued, would cross the bar at about four inches from where it is attached to the forceps. If the attachment were on the end of the handles, the axis

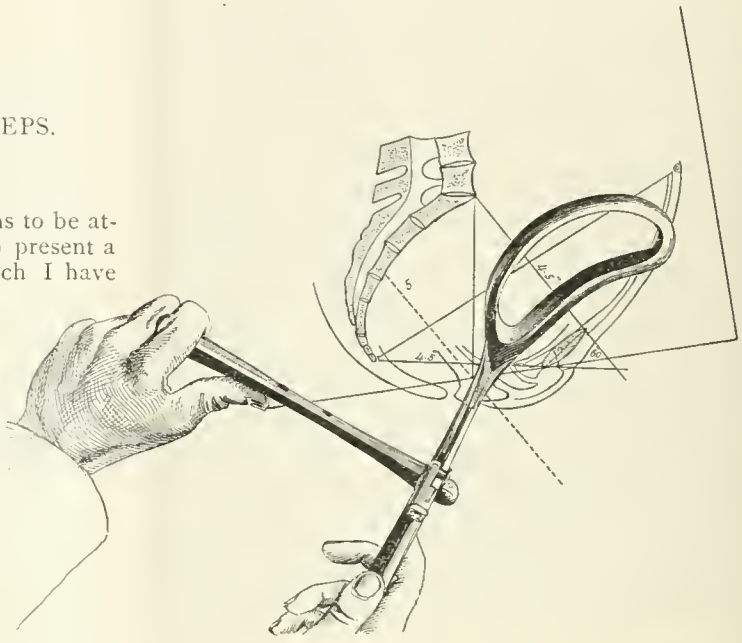

Fig. 3.

would cross the bar about eight inches from the forceps, if the handles are only four inches long.

We frequently see diagrams on a small scale which demonstrate, or are supposed to demonstrate, that the pull is in the axis of the inlet, but if they are drawn to scale with the normal diameters, we find that the traction is not always as it should be.

What I claim for this attachment, is that it can be applied to any forceps. That it is cheap. That the force is applied nearer the resistance than in any other method. The thumb-screw is not essential and can be omitted, as I did in the instrument I now use.

A SURGICAL NEEDLE ESPECIALLY ADAPTED FOR CATGUT.

By HENRY FLOOD, M.D.,

ELMIRA, N. Y.

Having used catgut extensively for a number of years, I have had excellent results by using the larger sizes; No. 3 being the size I prefer. All of my failures have been by using the smaller sizes for sutures, which often dissolve before firm adhesions have taken place. The sole objections I have found in the use of the larger sizes of catgut are, that it is difficult to find a needle with an eye large enough to be easily armed, and then, after the needle is armed, the doubled catgut at the eye of the needle is so thick that it sticks after the point and shank of the needle have passed through the tissues.

I have had George Tiemann & Co. make some needles which, from practical use, I have found completely overcome these objections. The needle is made after the plan of a spear. The point is lance-shape with cutting edges. It is made broader than the shank, and sufficiently wide to make a puncture large enough for

the doubled catgut at the eye of the needle to pass readily through. The shank is made nearly square, being flattened somewhat, so that a needle-holder can get a firm grasp and the needle cannot turn in the holder. The eye is made large and somewhat oblong, so as to be easily armed, and the needle at the eye is flattened so the doubled catgut will take up as little space as possible.

There are three shapes: The straight needle, the semi-curved, and the full-curved needle. The full- and semi-curved needles are made, commencing at the eye, with a straight shank for a distance long enough to give a firm grasp for the needle-holder, they are then curved.

My experience with the needle is that it passes through the tissues so easily that suturing can be done by hand, and that it is very seldom necessary to use a needle-holder.

MODERN MEDICAL AND SURGICAL CHEST FOR MILITARY USE.

DEVISED BY N. SENN, M.D.,

CHICAGO, ILL.

SURGEON-GENERAL NATIONAL GUARD ILLINOIS; EX-PRESIDENT ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES; PRESIDENT OF THE ASSOCIATION OF MILITARY SURGEONS OF ILLINOIS.

In the construction of this chest the author has sought to supply only such articles as are necessary in the modern treatment of medical and surgical cases, arranging them in the smallest possible space consistent with convenience.

FIG. 1.—Showing Chest with Cover Elevated and One Box Removed.

The present outfit in use by the United States Army consists of two wooden, brass-bound chests, each 15 × 15 × 23 inches, the two weighing 185 pounds. The medicines, both fluid and tablets, are contained in ordinary French square glass bottles, each bottle enclosed by a wooden partition, these partitions arranged in drawers and the drawers surrounded by proper framework, the latter constituting the body and partitions of the chest. It will readily be seen that the actual space occupied by the tablets contained in any one of these drawers, provided they were placed in a solid mass, would be but a small percentage of the room occupied by the drawer and its surrounding woodwork. Not only does this system require several times as much space as is necessary, but the weight is increased many fold.

To obviate these difficulties all remedies in tablet form are contained in tablet boxes, as shown in the illustration. These boxes are made of aluminum, in the ordinary form of slide powder-boxes, so arranged that the inner portion can only slip in one direction, and then only for the space of one inch (thus effectually preventing the accidental spilling of contents), while a paper lining prevents the medicinal substances from coming in contact with the aluminum. In addition to an inner descriptive label, each box is stamped with the name of contents, and also with a number. The latter facilitates the selection of the remedy wanted, as a list of tablets, alphabetically arranged in a table of contents is supplied with the chest. These boxes are of two sizes, designated large and small, the former containing about 300 two-grain tablets and the latter about 200.

FIG. 2.—The Truax Tablet Box.

The fluid medicines are principally contained in metal bottles, each spun from a single piece of aluminum. Tightly-fitting corks are supplied, each held in place by a metal clamp, on each of which is stamped the name of the contents. An illustration of this package, herewith, exhibits its advantages.

FIG. 3.—Aluminum Bottles for Fluids.

It is evident that the present United States Army outfit is not only much larger and heavier than necessary, but being composed of wood it is easily broken, subject to the action of rain and climatic changes, and in many ways undesirable. The chest here illustrated is 12½ × 12½ × 19 inches, weighs with contents 76 pounds, and contains practically all that may be found in the two above referred to. The wooden framework of the United States Army chest is here replaced by leatherine, heavily shellacked, thus rendering it impervious to water. Outside the leatherine is laid a sheet of aluminum, the joints of which are set in white lead, that the chest may be as nearly waterproof as possible. The body of the chest is held in place by a skeleton frame of untempered steel. To this framework the sides, ends, bottom, and top are firmly riveted with brass rivets one inch apart. An inner lining of aluminum extends around the chest, having a space between it and the leatherine of about one-fourth inch. When complete, this space is filled with felt and wire gauze, either of which may be used for splint material. This filling also provides a semi-elastic lining, thus assisting in preventing breakage of contents in concussions. Strong wrought-iron handles have been provided, that the chest may be packed on horses or mules for mountain transportation. This chest not only possesses a degree of lightness not found in other combinations, but it is practically imperishable and unbreakable. It is capable of being

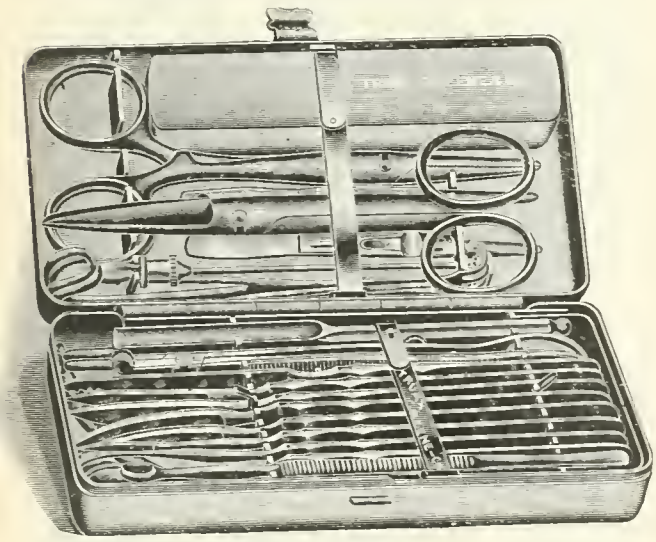
bent and straightened into form to a very large degree, and it will, without injury to its contents, withstand an amount of misuse that would completely demolish a chest of wood or similar material.

The contents of the chest are arranged in nine compartment-boxes, each provided with a cover and each resting on end, so that the removal of one may not disarrange the entire number. These boxes are of unequal width, thus "breaking joints" in the arrangement. Each is numbered, that no difficulty may occur in replacing them in their proper position. The cover of one is two inches deep, with soldered joints, that it may be used as a wash-basin. In addition to this a soft-rubber basin, 5 × 9 inches, is included in the contents.

The dressings, plasters, and in fact all articles comprising the outfit, are compressed into the smallest possible space consistent with the nature of the article.

The author's pocket operating-case is a model of compactness, and represents modern ideas, not only in surgery but in surgical mechanics. Although the case is but 1¼ × 2½ × 5 inches, and weighs only 19 ounces, by consulting the list of instruments it will be seen that it contains seven hæmostatic forceps, gouge for operations on the skull, forceps and probes necessary for the extraction of bullets, a periosteal elevator, bone-scoop, combined catheter, and such instruments as are necessary in amputations or battle-field laparotomies.

Such instruments as require locks are constructed with the new aseptible design that permits of the speedy separation of the blades and an accurate adjustment when in use. The knives are forged from a single piece of steel, and are of the highest possible quality and finish. The case containing the instruments is manufactured of German silver with well-rounded corners and edges. The racks containing the instruments are removable, that the case may be used as a tray to be filled with antiseptic fluid.



Author's Pocket Operating Case.

While the author contemplated in the construction of this case the performing of any operation with the knives therein contained, an additional knife with a large blade has been provided. The handle of this knife is designed so that the blade may be easily separated for cleansing, and a saw-blade has been furnished that may be attached to the same handle.

No pains have been spared in the selection of the various articles contained in this chest to furnish the most desirable instruments and supplies, regardless of price. All articles are carried in stock by the manufacturers in packages of the same size and form as those contained in the chest, so that duplicates that will fit the spaces may be secured at any time.

The author's pocket operating case contains:

- 2 Kocher's artery forceps.
- 1 Spring dressing-forceps slide-catch, 3 teeth.
- 1 Spring dressing-forceps slide-catch, 5 teeth.
- 1 Straight scissors.
- 2 Exploring trocars.
- 2 Double retractors, sharp and blunt.
- 1 Gouge for operating on the skull.
- 2 Serresfins.
- 1 Bulldog artery forceps and needle-holder.
- 1 Director and tongue-tie.
- 1 Little's saw.
- 1 Scalpel.
- 1 Straight sharp-point bistoury.
- 1 Curved, sharp-point bistoury.
- 1 Curved, blunt-point bistoury.
- 1 Tenotomy knife.
- 1 Aneurism needle.
- 1 Tenaculum.
- 1 Fenestrated bone-scoop and periosteotome.
- 1 Ear-hook and curette.
- 1 Pair of Senn's bullet-probes, porcelain heads for No. 22 and No. 38 calibre bullets.
- 1 Male and female catheter.
- ½ Dozen straight triangular needles.
- ½ Dozen straight round needles.
- ½ Dozen assorted curved needles.
- 4 Sizes silk on metal cards.
- ½ Dozen silkworm gut ligatures.

The above contained in a solid German-silver case with removable trays. All instruments with aseptible handles and joints.

The following is a list of contents of chest:

Surgical Instruments.

- 6 Catheters.
- 1 Caustic-holder, aluminum.
- 1 Set metal cuppers, 3 in set.
- 1 Hypodermic syringe in upright metal case.
- 1 McLean's amputating knife.
- 8 Ligatures, catgut.
- 2 Cards assorted ligatures, silk.
- 1 Dozen needles and needle-holder.
- 1 Soft-rubber pus-basin.
- 1 Razor-strop.
- 1 Heavy rubber bandage.
- 1 Saw to fit knife-handle.
- 1 Scissors.
- 1 Stethoscope.
- 1 Stomach-tube.
- 1 Senn's pocket operating-case.
- 1 Fever thermometer.
- 1 Tongue-depressor.
- 3 Tooth forceps.
- 1 Chain tourniquet.
- 1 Transfusion-tube.

Dressings, Plasters, Etc.

- 100 Antiseptic tablets.
- 4 Bandages, Esmarch's.
- 4 Bandages, flannel.
- 2 Pounds bandages, roller.
- ½ Pound cotton, absorbent.
- 3 Yards drainage-tubing.
- 4 Esmarch's first-aid packages.
- 10 Yards gauze, corrosive sublimate.
- 8 Yards gauze, iodoform.
- 1 Pound jute.
- 1 Box iodoform, sprinkler top.
- 1 Yard muslin, in sheet.
- 5 Yards paper, dressing.
- 1 Paper pins.
- 3 Dozen safety-pins.
- 40 Yards plaster, adhesive.
- 1 Yard blister plaster.
- 10 Yards plaster, Isinglass.
- 2 Yards plaster, mustard.
- 2 Pounds plaster Paris, splint material, wire and felt.
- 10 Sponges.
- 1 Piece tape.

Miscellaneous.

- 1 Hand-brush.
- 6 Candles.
- 1 Corkscrew,
- 1 Metal medicine-cup.
- 2 Goggles.
- 1 Graduate.
- 1 Lantern with oil.
- 1 Copy Carpenter's "Medicine."
- 1 Sail-needle.
- 1 Pencil, indelible, with leads.
- 12 Pencils, camel's-hair.
- 1 Heavy shears.
- 1 Spatula.
- 1 Pocket stove.
- 1 Copy Pilcher's "Surgery."
- 3 Suspensories.
- 1 Bulb syringe.
- 1 Fountain syringe.
- 6 Penis syringes.
- 1 Metal tape-measure.
- 1 Teaspoon.
- 1 Set universal towels.
- 2 Towels.

Sundry Drugs and Supplies.

- 8 Ounces carbolic acid.
- 8 Ounces alcohol.
- 8 Ounces concentrated ammonia.
- ¾ Pound beef extract.
- ¾ Dozen bottles, prescription and corks.
- 1 Dozen boxes for ointment.
- 1 Lot labels for prescription bottles.
- 4 Ounces magnesia sulphate.
- 1 Pocket medicine-case, filled.
- 1 Dozen nitrate of amyl, pearls.
- 1 Pound petrolatum.
- 1 Block prescription blanks.
- 1 Reagent-case.
- 8 Ounces castor-oil.
- 8 Ounces chloroform.
- ½ Dozen corks, large.
- 1 Block diagnosis-tags.
- 1 Lot envelopes for tablets.
- ½ Ounce iodine.
- 3 Packages salt for transfusion.
- ½ Ounce silver nitrate.
- 4 Packages soda carbonate, for sterilizing.
- 8 Ounces soap, castile.
- 8 Ounces turpentine.
- 8 Ounces whiskey.

Compressed Tablets.

- Acetanalid.
- Acid, arsenious.
- Acid, boric.
- Acid, tannic.
- Alterative.
- Ammon. chloride.
- Antipyrine.
- Bismuth. subnitrat.
- Blue-mass.
- Cafbromalid.

Calomel.	Morphine.
Camphor and opium.	Nitro-glycerine.
Capsicum.	Peptic.
Cathartic comp.	Phenacetine.
Chloral.	Podophyllin.
Capaibic comp.	Potassium, bromide.
Cough.	Potassium, chlorate.
Croton oil.	Potassium, iodide.
Diarrhœa.	Quinine.
Digitalis.	Salol.
Dover's powder.	Soda, bicarbonate.
Hypodermic, six varieties.	Soda, salicylate.
Ipecac.	Tonic.
Lead acetate.	Zinc, sulphate.
Liniment.	

TABLETS FOR HYPODERMIC USE.

Apomorphine, hydrochlorate.	Morphine, hydrochlorate.
Atropine, sulphate.	Pilocarpine, hydrochlorate.
Cocaine, hydrochlorate.	Strychnine, sulphate.
Ergotine.	

OPHTHALMIC DISCS.

Atropine, sulphate.	Eserine, sulphate.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 9, 1895.

	Cases.	Deaths.
Typhoid fever	7	2
Scarlet fever	115	15
Cerebro-spinal meningitis	0	5
Measles	159	13
Diphtheria	196	37
Small-pox	2	0

A Daily Medical Journal occasionally appears upon the horizon but does not stay there long. Philadelphia is the latest home of daily medical journalism. *The Daily Lancet* is edited and published by Dr. Joseph F. Edwards.

What Doctors Die From.—An abnormally high death-rate from tuberculosis is reported to exist among medical men in Russia—fifteen per cent. of the whole number of deaths being assignable to that cause. Zelande has lately presented some most valuable statistics calculated for three years, upon a consideration of the whole profession, some fifteen thousand odd. Nearly thirty-three per cent. of deaths were due to virulent diseases—pyæmia, typhus, cholera, diphtheria, etc. The prevalence of suicide—over eight per cent.—too, is strange. The *Medical Press* suggests poverty as a possible cause for this self-destruction; and in harmony with such an inference is the French experience that a large majority of suicides is due to want or fear of want. Perhaps the most satisfactory feature of the vital statistics of physicians is the statement of Bertillon, that though medical men do not apparently enjoy longer life than many others, their children display a singular immunity from disease.—*Medical Magazine.*

Medical Freemasons in New York.—In the Kane Lodge, of New York, says the *New York Medical Journal*, there are perhaps more medical brothers than in Æsculapius Lodge, of London. This seems eminently appropriate, as the lodge was named in honor of Dr. Elisha Kent Kane, of the United States Navy, the arctic explorer, and its membership, which includes some of the most prominent men in clerical, legal, scientific, financial, and commercial circles, would be incomplete but for representatives of the medical profession whose names are known and honored wherever the English language is spoken. This is not surprising, for those that are Masons can easily recognize how the principles of Freemasonry would appeal to a medical man.

The Medical Faculty of the University of Paris opened its doors to women in 1868, but at first only a very few availed themselves of the privilege thus offered. In 1878 the number in attendance was 32; during the next ten years (1878 to 1888) it increased to 114, and is at present 183, of whom the great majority (167) are Russians. The remainder are Poles, Rumanians, Servians, Greeks, and Scotch, and only one German.

The Doctors of the National Guard of the State of New York.—From an officer of one of the regiments we have received a letter in which he says that it seems to him that at this time it is very appropriate to have some mention made in the medical journals of the medical officers of the National Guard. He does not think that the general public is aware of the sacrifices they have to make—unless it may be their patients whom they have to neglect during their absence. He says that in his experience he has found the surgeons particularly attentive, not only to their medical duties, but also to their military duties. They are always, he testifies, exceedingly faithful, and their moral support to the commanding officer is much greater than is supposed. There is no member of the staff, he adds, to whom the commanding officer can so readily appeal as to his surgeon. The surgeons help him in the discipline of his command, and of course in the sanitary and commissary departments they are invaluable. Every article of food is passed upon by the surgeons, the cleanliness of the posts comes under their observing eyes, and they share with the rest of the command every danger.—*New York Medical Journal.*

Senator Gallinger on Antitoxin Again.—An editorial writer in the *Boston Herald* of February 6th, in speaking of Senator Gallinger's views on the future of antitoxin, made the following statement: "It is shockingly bad taste that Senator Gallinger, of New Hampshire, displays in speaking slightingly of the medical profession, of which he is the sole representative in the United States Senate. In voting an appropriation for the production of antitoxin in the District of Columbia, his lay associates in the Senate showed considerably more respect for the science of medicine than the one person in that body to whom the public would most naturally look for an intelligent action on this subject." The Senator writes in defence of his position that he is in good company in his views, having on his side Dr. Hansemann, of Berlin, assistant to Professor Virchow, "the dean of modern pathology." The *Boston Medical and Surgical Journal* criticises Dr. Gallinger for calling Virchow a "dean." Our contemporary shows unexpected limitations in its vocabulary. The eldest man in any branch of learning or profession is often termed its "dean" by way of courtesy.

Preparing the Antitoxin.—On October 12th, the Pasteur Institute possessed for immunizing purposes a stud of twenty horses. This stud has now been increased to one hundred and thirty-six horses, a total that will probably be ultimately increased to the maximum of 150. Fifteen of these animals are at the State Veterinary School of Alfort, where they are kept under close observation (with regard to pulse, temperature, etc.), by Professor Nocard and his pupils. Forty-two horses are located in the old abattoirs of Grenelle placed at M. Roux's disposal by the Municipal Council of Paris. Of these, twenty are kept by the municipality at a cost of 20,000 francs ($4,000) a year for the benefit of the Paris hospitals and poor. At Villeneuve-l'Étang—a property ceded by the State to M. Pasteur in 1886—there are seventy-nine horses cared for by a capable veterinary surgeon and his staff. While the regulation

six litres of blood (yielding about half that quantity of serum) are being drawn from the jugular vein, the animal's attention is easily distracted by a handful of carrots, which he munches contentedly. On the day following the phlebotomy immunization is recommenced and continued for five days. A rest of fifteen days follows, and then another bleeding may be practised. That the animals flourish under this *régime* of good feeding and periodical bleedings is proved by the presence in good health at Alfort of a sturdy Brittany pony which has hitherto supplied no less than four hundred and twenty litres of blood.

Raid on Ohio Druggists.—On February 14th, nine druggists of Cincinnati, O., were arrested at the instance of the State Dairy and Food Commission. The accused are charged with violating the drug section of the pure-food law. The arrests are the result of investigations which have been going on for the last six weeks. Dr. J. A. Sterritt has general supervision of the inspection of drugs for the department. Drug-stores in all parts of the city were visited, and samples of goods were obtained for analysis. In all between one hundred and seventy-five and two hundred samples were turned over to the department's chemist. Included in the lot is a wide variety of drugs and medicines. The work of analysis is far from completed, but of the samples so far examined about one-third are below standard or adulterated. Ohio is very keen on its drug and food adulterations, and it arrested some druggists for selling undistilled water. But it lets quack doctors riot through the State, because they have the "pull." Ohio will soon vie with Kansas as the zany among the States.

Trilbyismus.—Trilby has become a sort of epidemic like the mind-cure, the fifteen-puzzle, the Lottie Collins song, and other fads. To those who know literature the book is good, but not wonderful; to those who know hypnotism the book is silly; in a year or two it will be nearly forgotten.

Masturbation in Very Young Children.—In response to an inquiry several letters appear in the *British Medical Journal* upon this subject. Dr. Heywood Smith writes: "In reply to your correspondent 'Alpha,' who writes in the *British Medical Journal* of January 19th on this subject, both as to the age of the patient and the treatment of this terrible trouble, I write to say that the youngest case I ever saw was a child, aged two years, brought in its mother's arms to the Hospital for Women many years ago. The child was ailing and fretting, and its expression bordered on imbecility. I first of all ringed the clitoris, passing a silver wire through it and twisting it over a pen-holder. This had the desired effect for a time, as it prevented the child touching itself for a fortnight. At the end of that time, however, she began the old habit again, when I removed the ring and gave bromide of ammonium and tincture of Indian hemp, with the result that the child got quite well, the expression becoming quite rational." Mr. Alex. D. H. Leadman writes: "'Alpha' should try painting the clitoris and meatus with a twenty per cent. solution of cocaine; and if he will write to me I can supply him with several details too lengthy to occupy your space." M. R. C. P. writes: "Masturbation, judging from the testimony of intelligent anxious parents, can undoubtedly occur in a little girl aged eight or younger. It may probably occur as early in childhood as sucking the thumb, and with as little vicious intention. In the *British Medical Journal*, 1889, vol. ii., p. 1315, I referred to successful treatment by means of a 'cage,' secured in its place by lock and key, and worn at night or when the child is alone, so as to render the practice impossible. When any suitable case comes under my notice I continue to recommend such an appliance with good results. To prevent the mischievous first departure, caution should be adopted in regard to leaving little girls alone with big boys. Children, especially little boys, should not sleep with unworthy nurses."

Income of Washington Physicians.—A few weeks ago we mailed a letter to each of ten physicians of this city, whom we selected because of their wide acquaintance with the local profession. In this letter we requested answers to four questions, based on their observation during the past five years. Replies were received from eight, and with the exception of the answers to the fourth question, the remaining ones were remarkable in their close accord. The following are the questions and the average answers to the same: 1. What is the average professional income of the ten regular physicians of this city who have, in your opinion, the largest practices? $9,500. 2. What is the average professional income of the next one hundred physicians? $3,500. 3. What is the average income of all the regular physicians of this city? $2,000. 4. What per cent. of all regular physicians in the city do not derive a livelihood from their professional incomes alone? Answers to this varied from two to thirty per cent.—*National Medical Review.*

The Troubles Encountered in Colonizing Lepers are very great, in Louisiana at least. Indian Camp, where the Louisiana hospital for lepers has been established, is on the Mississippi River and in the parish of Iberville. The main building is a fine old plantation house. Gardens and woods extend on all sides of it, and the scenery is Arcadian. With eight cottages included, there are accommodations for one hundred lepers, but the present colony is much smaller, victims of the disease showing but little disposition to put themselves under the care of the State. The health officers have always found the task of isolating lepers a difficult one. The last time an attempt was made to inspect a settlement on Bayou Lafourche the lepers fled to the swamps, and there was no reaching them. The announcement of the authorities that the State Hospital is now open has filled the unfortunate victims everywhere with dread, and it will be necessary to take many of them to Iberville by force. The inhabitants of this parish are also making the duty of the hospital staff unpleasant, refusing to supply the patients with food, which, in consequence, is brought direct from New Orleans. Moreover, the servants of the institution have been warned that they will be shot should they venture outside the hospital grounds.

The New Buildings for the College of Physicians and Surgeons.—The working plans for the new Vanderbilt and Sloane additions to the College of Physicians and Surgeons have been completed and ground has been broken for the erection of the new buildings. The addition to the Vanderbilt Clinic is to be built to the east of the present building, at the corner of Tenth Avenue and Fifty-ninth Street, and will connect it with the main building of the college. The three lower stories will be used as an extension to the dispensary, and will furnish rooms for section teaching by the clinical instructors. The upper stories of this building will be occupied by the departments of bacteriology, clinical microscopy, and normal histology.

To the east of the present college building will be erected an addition of four stories and basement. It will be in the main devoted to the department of anatomy. The basement will contain a clay-modelling room and the reference osteological collection. The first and second stories will be devoted to the museum of human and comparative anatomy, while the third floor will be used as a morphological laboratory, and research work will be carried on by the instructors and post-graduate students. The fourth floor will contain an extension to, and connecting with, the present classroom of practical anatomy. The Maternity Hospital will also be enlarged.

EXCISION OF THE LARYNX.

SIX CASES HITHERTO UNREPORTED, TOGETHER WITH THE ANALYSIS OF THREE HUNDRED ADDITIONAL CASES GATHERED FROM LITERATURE.

BY CHARLES A. POWERS, M.D.,

DENVER, COL.,

AND

GEORGE R. WHITE, M.D.,

NEW YORK.

SINCE the first operation by Watson, in 1866, total or partial extirpation of the larynx has been performed upward of three hundred times. It has been the subject of exhaustive study at the hands of many observers. In earlier years by Schierer,[1] Baratoux,[2] Salamoni,[3] Mackenzie,[4] and Solis-Cohen;[5] recently by Pinçonnat,[6] Kraus,[7] Taube,[8] and Wassermann.[9] It has found its chief indication in carcinoma, but in scattered instances has been employed in sarcoma, polypi, tuberculosis, enchondroma, stenosis, and necrosis. Of all reported cases a little over two-thirds have been complete.

In the provisional choice of operation, one is to be guided largely by the results of endo-laryngeal examination; but whatever the procedure chosen, preliminary tracheotomy is a prerequisite. In this nearly all authors agree, and it is interesting to note that of the 171 total excisions collected by Pinçonnat it was omitted in but 8. Its advantages are that the lungs become accustomed to the new manner of breathing, that the trachea becomes fixed to the anterior wall of the neck, and that time is saved when doing the larger operation. The tracheotomy should be made well below the isthmus of the thyroid gland, and the tube inserted should be of large calibre. The laryngectomy may follow the tracheotomy in from three to fifteen days. During the operation of excision the greatest precaution should be taken to prevent fluid from passing down the trachea into the bronchi. Safety in this is effected by numerous devices, of which the tampon cannula of Trendelenburg, or some modification of it, is most in favor. Many operators have relied on occlusion of the trachea above the tube by distended rubber balloon, sponges, or gauze packing. Whatever the method adopted, the greatest care should be taken to render it effectual, entrance of blood to the lungs being exceedingly liable to occasion a fatal pneumonia.

In the total excision the patient lies on the back with a pillow under the shoulders, the head being a little dependent. An incision is made in the median line from the hyoid bone to a point a little below the cricoid cartilage, and a transverse incision over the hyoid bone meets this at its upper end. On exposing the larynx the sterno-hyoid muscles are drawn to one side and severed close to their insertion. The soft parts are bluntly dissected from the larynx. Vessels are ligated as encountered. After the sides of the larynx become free, the inferior constrictor of the pharynx is to be cut close to its insertion into the thyroid cartilage. The trachea is next cut across, just below the cricoid, and drawn forward, while its lumen is well packed with sponges or iodoform gauze. The larynx is bluntly dissected from the deeper parts, until the upper corners of the thyroid are freed. Finally, the thyro-hyoid membrane is cut across and the larynx removed. The epiglottis is removed or left in place according to its condition. If it is desirable to see the inside of the larynx before removing it, the thyroid can be split down the middle and the sides held apart, while the upper end of the trachea is packed with sponges or gauze. The organ can then be removed piecemeal.

The partial operation is usually performed by splitting the thyroid down the middle, packing the upper end of the trachea, and then removing as much of the larynx as is desirable.

After the operation the upper end of the trachea is packed firmly with gauze to prevent blood and saliva from flowing into it, and the rest of the wound stuffed lightly with an antiseptic gauze. Bardenheuer,[1] Solis-Cohen,[2] and others attempt to prevent foreign material from entering the lungs by elevating the foot of the bed. Nutritive enemata are given for the first forty-eight hours, then a stomach-tube may be passed through the wound into the œsophagus and gastric feeding begun. The packing is removed from the wound as often as necessary, and the parts washed with a weak antiseptic solution.

Breathing is maintained through the tracheal-tube for the first three or four weeks; an artificial larynx may then be inserted. The first apparatus of this kind was invented by Gussenbauer for Billroth's original case in 1872, and some modification of it is still in use.

In June, 1893, Hans Schmidt[3] exhibited a patient in whom there was no communication between the mouth and the trachea, in spite of which fact a fairly good voice had returned about a year after operation. Examinations by Helmholz, Landois, Fränkel, and others showed that the upper part of the œsophagus served as a receptacle for air, which put in motion some bands of mucous membrane at the base of the tongue. Solis-Cohen,[1] Carmalt,[5] and others have shown similar cases, and it is believed that by systematic practice a considerable number of these patients will recover their voice to a greater or less extent, without the aid of the artificial larynx.

The most frequent cause of death after the operation is pneumonia; it is due to blood or septic material entering the bronchi. In a certain number of cases fatal heart failure comes on four or five days after the operation. The cause of this has been exhaustively studied by Grossmann,[6] who thinks it due to irritation of the superior laryngeal nerve by contraction of the scar. Experiments on dogs show that stimulation of

this nerve always increases the blood-pressure, and in a certain number of cases renders the left ventricle insufficient, so that pressure in the pulmonary vein is increased and the lungs are congested, as shown by their increase in size. This stimulation, continued for a considerable length of time, can cause profound disturbance of the function of the heart, and finally complete cessation of its action.

The following six cases of excision of the larynx are here reported in full for the first time. One only, the first, was done by me (C. A. P.). The remaining five were observed by me in the practice of Dr. W. T. Bull, to whom grateful acknowledgment is herewith made for permission to publish.

Case I. *Partial Laryngectomy for Cancer—Death from Recurrence at End of Five Months.*—F. H——,[1] male, aged fifty-four, was referred to me by Dr. George A. Richards, December 28, 1891. His general health had always been good. He was a machinist, and had worked at his trade, mostly in brass-work, since boyhood. He had never suffered from syphilis nor been given to alcoholic or other excesses. He had never had more than a transient trouble in his throat until May, 1891, at which time he began to suffer with a persistent hoarseness and irritation. For a time he was unable to speak aloud, but later regained his voice. Expectoration was troublesome, and at times profuse. There was occasional pain in the throat, extending thence to the right side of the neck and head. When first seen by Dr. Richards there was a small oval mass on the right side of the larynx, between the cords. To exclude syphilis, potassium iodide was given in considerable doses. Under its use iodism developed and the tumor increased in size. The patient was examined by Drs. Lefferts and Delavan, who agreed with Dr. Richards in the diagnosis of cancer and advised extirpation. He was admitted to the New York Cancer Hospital, January 2, 1892. A preliminary tracheotomy was done well below the isthmus of the thyroid, and a long tracheal tube of large calibre inserted. This occasioned no reaction, and the patient was up and about on the third day. He breathed freely through the tube, but the irritation in the larynx increased and caused much discomfort at night. On January 13th, eleven days after the tracheotomy, the right half of the larynx was excised in the following manner: Chloroform being administered through the tracheal tube, an incision was made in the median line from the hyoid bone to a point three-fourths of an inch below the cricoid cartilage. The soft parts over the thyroid cartilage were somewhat thickened and infiltrated. The upper notch of the thyroid was defined, an angular scissors entered at the crico-thyroid space, and the thyroid cut in the median line from below upward. At this first cut the cavity of the larynx was not entered, and as it was thought possible that the incision might be somewhat lateral, an additional cut was made on its left. It was found that the growth passed beyond the median line and thus occasioned deception. The two halves of the larynx were held widely apart with retractors and the trachea immediately stuffed with small sponges to the level of the tube.

Examination of the larynx showed a soft, grayish mass with segregated surface ulcerations, which extended from the upper to the lower border of the right thyroid wing, passing somewhat beyond the median line anteriorly, and at the centre bulging well toward the opposite side. A transverse cut was made above, outward to the edge of the sterno-mastoid, and the soft parts dissected from the outer surface of the thyroid cartilage. The thyro-hyoid membrane was cut across and the right half of the larynx easily removed, the pharynx being opened anteriorly and above. The right half of the cricoid was also taken away, together with the anterior portion, about one-fifth, of the left half of the thyroid. The left vocal cord was reddened, but the tissues seemed free from infiltration. Hemorrhage was checked, the wound washed with Thiersch's solution, and mopped out with a one-fiftieth per cent. sublimate solution. The sponges were removed from the trachea and a rubber balloon inserted and inflated, iodoform gauze being packed pretty tightly above it. The balloon had a diameter a little larger than the lumen of the trachea, and when blown up seemed to occlude the tube admirably. The rest of the cavity was packed firmly with iodoform gauze. The patient recovered rapidly from the chloroform, and showed no signs of shock. Rectal feeding was commenced early and carried out in the usual way. The outer dressings were quickly stained from oozing, and were changed at frequent intervals. The mouth was kept clean by constant washing with boric-acid solution. During the night a small amount of clotted blood was coughed through the tracheal tube. The temperature and pulse during the next five days were but little above the normal, the enemata were well retained, and the patient was comfortable. On the fourth day the gauze was removed, a soft rubber catheter passed through the wound into the œsophagus, and stomach-feeding with peptonized milk and whiskey commenced. On the fifth day the patient expelled a very considerable amount of blood through the tracheal tube. The temperature ranged from 100° F. to 104° F., the pulse ran up to 120, and septic bronchitis was feared. Physical examination of the lungs gave negative results.

These unpleasant symptoms gradually subsided, but unmistakable signs of iodoform poisoning were seen. The dressing was removed and gauze wet in Thiersch's solution was substituted.

On the eleventh day a severe secondary hemorrhage took place. This was promply checked by the house surgeon.

On the fourteenth day an œsophageal tube was passed through the mouth and left in place. At the end of the third week he was able to swallow soft food. An artificial larynx, a modification of Gussenbauer's, was inserted, and the opening in the trachea allowed to close. The apparatus proved satisfactory. The wound contracted upon it, and with its obturator in place the patient was able to swallow without difficulty. He could speak in a hoarse monotone, which was quite intelligible to those near by. The tube was of large calibre and the ingress and egress of air were ample.

The patient returned to his home, but a recurrence of the growth took place, and he died five months after the operation.

Report of the hospital pathologist, Dr. Coleman: "Epithelioma."

The remaining five operations were performed, as said, by Dr. Bull.

Case II. *Total Laryngectomy for Cancer—Death at End of one Year.*—W. W——, aged sixty-two, engineer. June 17, 1887. About a year and a half ago began to lose his voice. Ten days ago began to have difficulty in breathing.

Examination by Dr. Beverley Robinson: Two cauliflower-like excrescences on the right side of the larynx, the superior taking its origin from the ventricular band, protrudes into the larynx, filling nearly half of the lumen. The lower growth is below the vocal cord and occludes the larynx to a greater extent than does the upper.

Tracheotomy under cocaine.

Endo-laryngeal Operation.—June 18th. Incision in the median line down to the thyroid cartilage, which was divided with a heavy scissors. In addition to the two growths above described another was found on the left side just below the vocal cord. The growths were removed with a Volkmann spoon and the bases touched with a saturated solution of chromic acid. The cartilage was united with a silver-wire suture and the superficial parts closed with catgut. Uneventful recovery.

[1] This case was shown before the Section on Laryngology, New York Academy of Medicine, in 1892.

The tube was removed on the fifth day, and the patient left the hospital relieved of dyspnœa.

Pathologist's report shows both growths to be epithelioma, cells of the small flat variety.

July 26th.—Dyspnœa and loss of voice. Tracheotomy under cocaine.

Total Laryngectomy.—August 3d. The patient was placed on his back with his head slightly dependent. An incision was made in the median line from just above the hyoid bone to the tracheotomy wound, and a transverse incision along the hyoid bone. The edges of the wound were retracted and the muscles peeled from the thyroid cartilage with a periosteal elevator. The thyroid was split in the median line without going through the mucous membrane, and the soft parts separated from the inside of the cartilage, which was then taken out in pieces. The larynx was opened by an incision from the hyoid bone to the cricoid cartilage, and the lumen of the trachea above the cannula filled with sponges and iodoform gauze. The growth was now examined and found to extend from the apex of the right arytenoid forward and to the right as far as the median line in front; downward as far as the base of the arytenoid, and to the left as far as the middle of the cricoid. There was another deposit half an inch in diameter about the insertion of the true cord. The cricoid was divided in the median line and its external attachments dissected off, then split posteriorly, and detached from the anterior wall of the pharynx, together with the parts of the larynx above it. The thyro-hyoid membrane was cut close to its lower attachment and the entire larynx removed. The lumen of the trachea was plugged with iodoform gauze above the Trendelenburg cannula, and some lamp-wicking placed above this, the rest of the wound being lightly packed with iodoform gauze. A loop of silk was passed through the anterior wall of the pharynx to facilitate the passage of the stomach-tube; sutures to the transverse wound; nutrient enemata for the first twenty-four hours; afterward feeding by stomach-tube.

Uneventful recovery. Death from recurrence about a year later.

Case III. *Partial Laryngectomy for Cancer—Death in Fourteen Months.*—J. D——, male, aged fifty-one. March 20, 1888. Four months before admission to the New York Hospital the throat became sore; no cough, no dyspnœa, but slight pain on swallowing. Three weeks ago hoarseness and slight laryngeal cough. Dyspnœa during last two weeks. Upon admission the patient had extreme dyspnœa and a moderate degree of cyanosis.

Examination: The parts about the base of the tongue are somewhat tumefied and congested. The apex of the epiglottis is pushed to the left by a growth which involves its inner surface, and extends downward and to the right as far as can be seen. There is but a very narrow slit between the growth and the opposite half of the larynx. There is a distinct enlargement of the glands on the right side of the jaw. A low tracheotomy was performed under cocaine to relieve the urgent dyspnœa.

Partial Laryngectomy.—March 31, 1888. The tracheal tube was packed about with sponges to prevent blood from entering the trachea. A vertical incision was made from the hyoid bone to a point just above the tracheotomy wound. The thyroid cartilage was split in the median line and the sides held apart by retractors, exposing the growth, which was found to involve the right side only and extend as far down as the base of the arytenoid. The epiglottis was drawn down by a hook and found to be involved. The left half of the larynx, together with the epiglottis and part of the wall of the pharynx, were removed and the wound packed with iodoform gauze. Condition of patient during and after the operation was excellent.

Feeding by stomach from the first day. Uneventful recovery. Death from recurrence in fourteen months. Pathological diagnosis: "Epithelioma."

Case IV. *Partial Laryngectomy for Sarcoma—Well at End of Four Years.*—L. R——, aged forty-three, female. The patient first came under observation April 5, 1888, at which time she complained of hoarseness of several months' standing.

Examination showed tumefaction of left ventricular band with degeneration of left true vocal cord. Mucous membrane high colored on the left side.

June 26, 1888.—Tracheotomy under chloroform, and a long silver tube inserted.

Partial Laryngectomy.—July 4, 1888. Head dependent. Incision from half an inch above hyoid bone to half an inch above tracheotomy wound. The larynx was split its entire length, and the upper end of the trachea was packed with sponges. The vocal cords appeared normal, but in the left ventricle and false vocal cord there was evident thickening, but no sharply defined tumor. A section of the ventricular band was removed, and after freezing, sectioning, and staining was found to contain inflammatory tissue only. The mucous membrane was normal. In view of the fact that the larynx had been the seat of a tumor for some weeks, which had been slowly increasing in size, it was thought best to excise all of the suspicious area. Between the true and false vocal cords a small mass of tissue was found about the size of three peas; this appeared to be attached to the cartilage. A section of this was rapidly prepared by Dr F. Ferguson, and gave evidence of being a small, round-celled sarcoma. Half of the larynx was removed with scissors, leaving behind the superior cornu of the thyroid. The wound was irrigated and packed with bismuth gauze. The upper angle was closed by two catgut sutures. The operation lasted two hours, a half of which time was spent in microscopical diagnosis. Uneventful recovery. Full pathological report lost. Patient well four years later.

Case V. *Total Laryngectomy for Cancer—Death from Recurrence at Two and One-half Months.*—J. L——, aged forty-four, male. Family and personal history good. Four months ago the patient began to have dyspnœa and dyspepsia. Two months ago tracheotomy was performed to prevent suffocation. He has worn the tube since. It has occasioned no trouble.

Examination by Dr. D. B. Delavan shows a large growth filling the upper part of the larynx, apparently attached on the right side and extending well over the median line. It is impossible to demonstrate where the growth is attached to the laryngeal walls, as they cannot be seen below the level of the top of the arytenoid cartilages. The depth of the tumor cannot be estimated. The epiglottis is fixed, showing no movement. Its shape, however, is normal. There is much congestion and some infiltration of the adjacent sides of and the pharynx. The surface of the tumor is irregular nodular. The mucous membrane is deeply congested.

Total Laryngectomy.—Operation: April 18, 1888. An incision was made in the median line, from the upper part of the hyoid bone to a point just above the tracheotomy wound, and a transverse incision along the hyoid joining the upper end of the first.

The soft parts were dissected from the larynx with periosteal elevator and the larynx split its whole length in the median line. The sides were held apart and taken out piecemeal until the cartilages and all the growth were removed. The epiglottis was left intact. The transverse incision and half of the vertical one were sutured with catgut, and the rest of the wound packed with iodoform gauze. The patient recovered well from the anæsthetic. He was given nutrient enemata the first thirty-six hours, after which he was fed by a stomach-tube.

May 2d.—Patient up and walking about.

May 11th.—The lower angle of the wound was enlarged with a cautery and a long tube inserted into the trachea through the wound.

The patient continued to do well until June 15th, when a small nodular mass was found at the right of the tracheal opening, adherent to the skin and mucous membrane. Examination showed the growth to be too extensive for removal.

June 27th.—The growth is the size of a goose-egg, and extends from the hyoid bone half way to the sternum. On the left side the skin is thickened, indurated, and firmly adherent. Induration reaches to the sternum.

June 30, 1888.—Patient died of hemorrhage from the growth.

Pathological diagnosis: "Epithelioma."

Case VI. *Partial Laryngectomy for Cancer—Death from Operation.*—J. V——, aged sixty-eight, male, New York Hospital. Family and personal history good. For a long time has had transient hoarseness on taking cold. Two years ago subsidence did not occur, a tumor was discovered by a laryngologist and pronounced benign. Hoarseness was the only symptom until three months ago, at which time dyspnœa was experienced.

Examination: A reddish-gray tumor is seen growing from the right vocal cord. No ulceration. No enlarged cervical glands.

Partial Laryngectomy.—November 10, 1890. A median incision three and one-half inches long was made, the lower extremity being opposite the third tracheal ring. Tracheal cannula inserted. Thyroid opened, disclosing a tumor involving the right vocal cord and the mucous membrane above and below it. The right half of the thyroid and right arytenoid were removed, leaving the superior cornu of the thyroid. The wound was packed with iodoform gauze.

The patient developed septic pneumonia and died the fourth day after the operation.

Pathologist's report: "Epithelioma."

In considering the question of result, immediate and remote, after laryngectomy, the writers have compiled statistics in all of the cases to which they have been able to gain access. They have taken as a groundwork the admirable article of Eugene Kraus,[1] who, in 1890, collected and carefully analyzed all of the cases which were accessible to him. Of these there are 240. The writers are able to add 69 cases, making a total of 309. The cases collected by them are appended to this article (Table C). Statistics of the entire number of cases are found in the following table (A):

Table A.—Total Extirpation of Larynx.

	Kraus.	The Authors.	Total.
Number of cases	160	48	208
Carcinoma	142	43	185

[1] Allg. Wien. med. Zeitung, Bd. 35, p. 109.

Of the 309 operations 101, or thirty-two per cent., of the patients succumbed to the operative procedure—died within the first eight weeks from shock, hemorrhage, pneumonia, septic infection, or exhaustion. The mortality was considerably greater in the total operation than in the partial, it being thirty-five per cent. in the former as against twenty-seven plus per cent. in the latter.

The mortality is, then, an important factor in weighing the matter of operation. That it must vary materially, and must be dependent to a not inconsiderable degree on the general condition of the patient, the nature and stage of the disease, and, indeed, on the surgeon, may well be thought. Unfortunately, we are unable to analyze and estimate these factors, and are forced to accept the figures as a totality.

The cases collected by the authors (late cases) show a decrease in the death-ratio in the total excisions: twenty-nine plus per cent. as against thirty-six per cent. in the Kraus tables; while the mortality in the partial operation is, on the other hand, markedly increased: thirty-eight per cent. as opposed to twenty-five per cent.

The fact that such a large percentage of the operators have had but a single case may possibly be accepted as contributory to an explanation of the high death-rate, and it is but fair to assume that more careful selection of cases, early operation, and a constantly improving technique will tend to diminish the mortality. For the present, however, we shall doubtless be unable to remove laryngectomy from the list of very serious operative procedures.

When we consider the question of ultimate results in the malignant cases we find the statistics very unsatisfactory. Cases which are to be of value should be traced to the end. Assuming, in common with other observers, that three years is a fairly safe limit, the cases should be divided into two classes: first, those prior to three years ago, and second, those done within the last three years.

In the following table (B) an exhibit is made of the laryngectomies done for carcinoma prior to January 1, 1892:

Table B.—Carcinoma.

1. *Total Excision of Larynx.*

Cases reported prior to January, 1892	180
Died as result of operation (8 weeks)	72
Died in first year, 5 from recurrence	8
Recurred in first year, either dead or still living when reported	51
Recurred after one year [13 months (2); 2 years (2); 2 years, 1 month; 2 years, 7 months; 3 years, 4 months; 9 years]	8
Reported in first year—free	16
Reported in second year—free	11
Reported in third year—free	3
Reported after three years—free	11

2. *Partial Excision of Larynx.*

Cases reported prior to January, 1892	77
Died as result of operation (8 weeks)	26
Died in first three years (3 from recurrence)	5
Recurrence in first year, either dead or still living when reported	17
Recurrence after one year [13 months; 16 months; 17 months]	3
Reported in first year—free	13
Reported in second year—free	4
Reported in third year—free	2
Reported after three years—free	7

Total Laryngectomy for Cancer. (Table B, 1.)—It is seen that of the 180 cases, 72, or forty per cent., died as the direct result of the operation itself. Of the remaining 108 cases, 51, or nearly one-half, had recurrence during the first year; and 11, or ten plus per cent., of the survivors were free from relapse three or more years after operation. These cases were as follows:

Operators: Bergmann, 3 years; Stoerck, 3 years, 3 months; Winiwarter, 3 years, 4 months; Fischer, 3 years, 6 months; Gottstein, 3 years, 6 months; Camponotto, 3 years, 6 months; Thiersch, 3 years, 7 months; Schede, 4 years, 6 months; Gussenbauer, 6 years; Gussenbauer, 6 years; Gussenbauer, 8 years (patient died of pleurisy).

TABLE C.—TOTAL EXTIRPATION OF LARYNX.

Cases Collected by the Writers.

No.	Surgeon.	Date.	Sex and Age.	Diagnosis.	Parts Removed.	Course.	Source.

[1] These cases are taken, as others in the same list have been found to be authentic when investigated.

Of the remaining cases, 8 died during the first year, without recurrence; 8 suffered relapse at a period varying from thirteen months to nine years; while the other 25 are reported before the lapse of three years, but are noted as "free"—16 in the first year, 11 in the second, and 3 in the third.[1]

Partial Laryngectomy for Cancer. (Table B, 2.)—Seventy-seven cases, of which 26, or thirty-three plus per cent., died during the first two months. Of the remaining 51, 7 cases, or thirteen per cent., are reported as "free" three or more years after operation. These cases are by Billroth, 3 years, 6 months; Stewart, 4 years; Schmidt, 4 years; Bergmann, 4 years; Solis-Cohen, 4 years, 3 months; Billroth, 4 years, 5 months; Küster, 8 years.

There remain the 10 cases subjected to operation during the past three years. (See Table C.)

It is worthy of note that in both the total and partial operations but two cases relapsed after the three-year limit had been passed, one at three years, four months, the other, Hahn's celebrated case, at the end of nine years.

It is more than probable that there are unrecorded fatal cases; it is not probable that there are many "cured" cases which have not been placed on record. So far as we can judge at present, however, we must accept these figures. Cases reported as "free" before the lapse of three years are of little value, except in that they diminish by so much the operative death-rate. And it would be of decided value if surgeons would divide their cases according to the extent of the disease. The writer (C. A. P.) has called attention to this on a previous occasion.[2]

It is obviously improper to include in the same category a case in which the cancerous process has progressed to the tissues outside the larynx and one in which there is a small intra-laryngeal epithelioma. In the one case there is no chance for cure, in the other a wide excision may offer a fair prospect of freedom from relapse.

In this way Kraus found that when the growth was confined to the larynx thirteen per cent. of the total operations and twenty per cent. of the partial were free from recurrence two or more years after removal. These percentages are based on the entire number of cases, deaths included, and are encouraging.

Of the operations for conditions other than carcinoma the following may briefly be said: There are 23 total laryngectomies. Sarcoma, 9—1 free at fifteen years; 1 free at twenty months; 1 free at three months; 6 died soon after operation. One case each of polypus, cicatricial stenosis, myxo-chondroma and chronic laryngitis (?) survived. The remaining cases succumbed to the operation.

The partial laryngectomies are as follows: Sarcoma, 3; enchondroma, 2; tuberculosis, 3; stenosis (syphilis—trauma), 11. Total 19.

One sarcoma case is "cured" at end of four years, 1 enchondroma, 1 tuberculosis, and 8 stenosis cases are noted as cured. The remainder died.

These conditions are, however, minor—the major interest lies in carcinoma, and we may ask, "How is the laryngologist or the surgeon to advise his patient?" He may, perhaps, explain to him the conditions shown by the foregoing figures—the mortality-rate, the ratio of recurrences and of "cures." So far as we now know, the only hope for the cure of cancer lies in its excision. A palliative tracheotomy leaves the patient without hope, he is condemned to a torturing death.

Czerny avers that his patients who suffered excision but who had relapse were more comfortable than those who had no operation.

[1] Of these, one, the famous case of Solis-Cohen, may now be added to the list of those past the three-year limit.

[2] On Cases Recently Admitted to the Surgical Service at the New York Cancer Hospital. New York Medical Journal, April 14, 1894.

It was the fortune of the writers to see, in the early part of 1894, Solis-Cohen's remarkable case—a man whose entire larynx and upper trachea had been removed for cancer over two years before. The man was in good health, free from recurrence.

Monks, of Boston, in a recent letter says that his case of partial laryngectomy is well and free over two years after operation. Such cases are worth scores of failures, if indeed the term "failure" can be applied in such an harassing and fatal affection. It is not so many years ago that surgeons advised against operation in cancer of the breast, while in a recent paper Bull[1] reports twenty-six per cent. free from relapse three to eight years after operation in all of his cases, unselected, and says that he feels that of the patients seen in the earliest stage of the disease fifty per cent. would come under the head of "cured."

It is not the purpose of the writers to strenuously advocate laryngectomy, but rather to make a plain statement of existing facts. Early diagnosis is of the greatest importance, and in many doubtful cases an exploratory thyrotomy will be found advantageous. It will be acknowledged, as said, that the only hope of cure, in cancer, lies in excision, and it is not irrational to expect that the progress which is constantly being made in the management of all forms of malignant disease will in due time enable us to record an increasing number of cases of cancer of the larynx free from relapse.

THE TREATMENT OF SUPPURATION OCCURRING IN THE COURSE OF TUBERCULAR JOINT-DISEASE OF CHILDREN.[2]

By HENRY L. SHIVELY, M.D.,

NEW YORK.

PHYSICIAN TO THE PRESBYTERIAN HOSPITAL DISPENSARY.

The proper management of suppuration in the various phases of chronic joint-disease necessitates a discrimination between cases developing in children and in adults. From this distinction there follows a natural division of cases based on pathology and clinical history which will help to harmonize conflicting views of treatment. In the child the processes of growth and repair are more active; complicating pulmonary disease is less frequently present; there is less danger of amyloid visceral changes; and on the other hand, the invasion of the joint by operative procedure, where it involves destruction of the epiphyses, results in progressive shortening of the limb as the child grows and is thus more serious than similar operations on the fully developed limb. Clinically the organism of the child is found to be better able to cope with the ravages of the tubercular infection; the prognosis of phthisis is usually better, and throughout it is generally observed that localized tuberculosis runs a more benign course in childhood. Again, the disease in joints and bone may be considered as more nearly resembling tubercular adenitis than tuberculosis of other organs, the histological elements of bone, especially the spongy portions, and the serous surfaces of joints, being closely akin to the lymphatic system in which phagocytosis and other natural eliminative and conservative processes are most active. For this reason possibly, the bacilli are so often difficult to detect in bone and joint-disease and the prognosis of uncomplicated tuberculosis in these parts, as in the lymphatic glands, is relatively much better than in other organs. Another serous membrane which it is well known is singularly tolerant of the tubercular infection, is the peritoneum, also richly supplied with lymphatics.

All of these considerations call for conservative methods, especially in children, and the avoidance, ex-

[1] MEDICAL RECORD, 1894.

[2] Read before the Manhattan Medical and Surgical Society, October 27, 1894.

cept as a last resort, of mutilating operations which are more often justifiable and necessary in the adult. It is for a more extended application of non-operative treatment I would make a plea and it will be the burden of this paper to show that with proper support and mechanical treatment, with due observance of good hygiene and nutrition, tuberculosis of joints even in the suppurative stage in children will rarely require other means. Indeed, the occurrence of abscesses when rightly cared for can hardly be said to exercise any unfavorable influence on the ultimate termination of the case. How often in orthopedic practice a pale, emaciated, anæmic child with thigh riddled with old sinuses, and painful deformity from neglected hip-disease, will make an excellent recovery with a useful limb when the general surgeon would have condemned the joint to operation. Such a case is the opportunity of the orthopedist and its successful management a triumph of patience and of prudent conservatism.

Without minutely considering the pathology abscesses may be classified as extra-articular, involving adjacent soft parts or more or less remote from the joint, as the ordinary "cold abscess;" and as intra-articular, originating in the epiphysis or synovial membrane of the joint. The pus of chronic tubercular origin is different in important respects from that of an acute abscess; it is less irritating, it is often readily absorbed and shows a tendency to desiccate and disappear spontaneously instead of pointing and opening externally. Indeed, where developing in the cavity of a joint it often appears as a gradual modification of the normal joint contents from increase of leucocytes. The old rule, *ubi pus ibi evacua*, in the light of modern research and experience cannot be held to apply in these cases. Yet how frequently in practice is the knife at once plunged into such an abscess, thereby often converting a localized tubercular process into a general infection through the freshly opened lymphatics of the incision or curetted surface. A comparatively harmless, encapsulated collection of pus may thus be changed into a profusely discharging and exhausting sinus from a fresh infection of the staphylococcus of suppuration, or a fatal meningitis or lung complication may supervene from dissemination of the tuberculous material.

In large abscesses it is best, then, in the absence of special indication as threatened invasion of a joint or proximity to a vital organ, to permit them to point and open themselves when absorption does not take place. By thus waiting for spontaneous evacuation a certain number will disappear, and in those which remain nature, by erecting in advance a barrier of healthy granulation-tissue, prevents the spread of diseased material from within and fresh infection from without. From this point of view, the opening and curettage of large abscess cavities often communicating by tortuous sinuses with diseased bone remote from the surface and precluding thorough removal of diseased tissue and perfect sterilization of the parts, appears irrational and unscientific.

The most familiar exceptions to this general expectant plan of treatment are in cases of retro-pharyngeal abscess complicating cervical caries where pressure symptoms have arisen, and in cases where an abscess is near enough a joint to be dangerous from contiguity. In the former instance, if deglutition or respiration become embarrassed, it is necessary to evacuate the pus promptly. This is best done by an incision from without at a point behind the sterno-mastoid muscle where this is possible. Incision through the pharynx is objectionable because in this situation drainage is imperfect, the wound cannot be kept aseptic and it is difficult to prevent the premature closing of the opening. The following case may be of interest as illustrating the expediency of incision where the healthy articulation is threatened.

Bella F——, aged five, is of good previous personal history, and there is no evidence of tuberculosis, bone or joint-disease in her family. One month after a fall a slight limp was detected in her right leg and there was some pain and tenderness about the hip—all of which symptoms were increased by use of the limb in locomotion, and have continued for six months and up to February 16th, when she was referred to me for treatment.

On examination the child is well nourished, there are no signs of acute inflammation, measurements of the limbs are the same, there is no atrophy, the thigh is held slightly flexed, adducted, and rotated inward. On passive motion, flexion is limited by sharp muscular spasm and joint function in all directions is incomplete. The diagnosis of incipient hip-joint disease was confirmed and a long extension-brace was applied with a high-soled shoe to the foot of the well limb. The patient a week later was doing well, pain and tenderness had disappeared and motion in all directions was less restricted. Progress was uneventful until May 4th, when for the first time a small, fluctuating tumor about the size of a pigeon's egg presented in the right gluteal region, a little above and internal to the great trochanter. This at first was deep-seated and obscure but gradually approached the surface and increased in size. As the abscess developed there was a notable improvement in the condition of the joint. Motion was soon as free as in the hip of the healthy limb and manipulation was free from pain.

On July 22d the abscess was opened and about two ounces of thin pus evacuated. The incision healed kindly under one dressing and up to the present time there has been no reaccumulation. The brace was continued until August 26th when it was removed as the joint appeared perfect in all its functions and free from reflex spasm. The patient was considered well and has since had no return of trouble in the joint.

In view of the speedy disappearance of symptoms and complete restoration of function in the later progress of this case no real involvement of the joint structure can here be premised. The condition which at first was indistinguishable from a true incipient coxitis was doubtless due to the irritation of peri-articular inflammation which resulted in the formation of an abscess external to the joint. With the opening of this abscess and free drainage the joint symptoms vanished. Operation in such a case is not only justifiable but is imperatively demanded to save the joint. In the case here narrated it is believed that escape of the joint from future infection was hardly possible as the abscess was very deep-seated and through the incision the finger could readily feel the capsule of the joint lying in close contact.

Treatment in general must be considered in connection with the primary disease and as a prophylactic measure of the first importance should be urged proper mechanical support providing rest and fixation for the diseased joint. To be efficient a sufficient length of limb above and below should be included in the immobilization. If a joint of the lower extremity be diseased the limb should be entirely relieved of weight-bearing either by recumbency in bed or by means of an axillary or perineal crutch. In short where destructive joint-disease exists there appears to be no good reason why in the application of braces and supports the same principles should not hold as govern the employment of splints in the treatment of fracture. The common practice of treating knee-joint disease by immobilizing in plaster of Paris and permitting use of the limb in locomotion and to support the superincumbent body, cannot be too strongly condemned. Likewise in ankle disease no device can insure sufficient protection which does not provide for complete relief from weight-bearing. The hip is usually treated on correct mechanical principles and it is inconsistent not to apply similar methods to the other joints of the lower extremity where the conditions are much the same. While not

denying the occasional development of abscesses in cases properly treated from an early period, yet suppuration is usually seen in neglected cases and in children the disease can generally be arrested before it reaches this stage if an early diagnosis is followed by efficient mechanical treatment. Even in old cases where numerous sinuses exist, often one of the first signs of improvement after fixation and support have been secured is a diminution or cessation of the discharge.

In the matter of mechanical support, whatever the preference of the individual orthopedist may be in the choice of materials, where complicating abscesses are present, there can be no doubt of the superiority of soft steel supports over plaster and its substitutes. Steel braces are lighter and admit of extemporaneous modifications which the ingenuity of the surgeon will readily devise in order to avoid pressure upon fluctuating points and interference with drainage where abscesses have opened. Their superior cleanliness, greater accuracy of adjustment and the facility with which they permit change of dressing leave no room for doubt if a discriminating choice is made. Valuable as is plaster of Paris in proper cases, I cannot but feel that its cheapness and the readiness with which it is applied, are responsible for much of the bungling work and bad results of orthopedic practice—witness the pressure sores, pent-up discharges, eczemas, anchylosis in faulty position and increasing deformity which are often found after the tardy removal of plaster splints. The tendency almost invariably in dispensary practice, is for the plaster dressing to go too long unchanged and thus the frequent inspection so necessary to careful treatment is neglected. When a limb is encased in a firm, immovable dressing of plaster often the fair, smooth exterior is a veritable whited sepulchre concealing foul discharges, sloughs and vermin beneath. That these are not imaginary or theoretical objections was well shown in a case of mid-dorsal Pott's disease which came to me recently. The child had been treated in the out-patient department of one of the city hospitals where a heavy plaster jacket with jury-mast attachment had been applied. The child had emaciated, in consequence of which the jacket had become loose and no longer available as a support. When the plaster was removed the summit of the kyphos, which the father stated had rapidly increased, was marked by a sloughing pressure sore through which the spinous process of a dorsal vertebra was nearly protruding. It would hardly have been possible for such a condition to have developed with the Taylor spinal brace or Thomas cuirass and have escaped observation.

Simple aspiration of abscesses is usually unsuccessful as the pus is often thick and curdy, clogging up the needle, or the cavity rapidly refills necessitating repeated operations. Aspiration with injection of antiseptics has found more favor in recent years. Of these the following have been used: Carbolic acid, chlorine, boracic acid, arsenic, mercuric chloride, creosote, guiacol, chloride of zinc, camphorated naphthol, iodine and iodoform. Practically, all but the last have been abandoned. Iodoform was first used in ethereal solution which, on account of its irritating effects and the report of a number of cases of iodoform intoxication, has fallen into disuse. At present iodoform solution in sterilized olive-oil or glycerine, strength ten to twenty per cent., appears to constitute a really valuable addition to treatment and should be tried after immobilization fails to effect further improvement. The injections are to be repeated at intervals of a week or ten days, five or six being usually necessary. Frequent failures and disappointments are reported. For discharging sinuses, peroxide of hydrogen besides thoroughly disinfecting, promotes separation of sequestra, limits the discharge and stimulates healing. It may be employed in five to ten per cent. solution. Fistulous tracts may also be injected to advantage with ten to twenty per cent. solution of zinc chloride. For pouting, tender granulations and sodden eczematous areas about the mouths of old sinuses, subiodide of bismuth, europhen, aristol and dermatol are among the best local applications. They are better in powder form than in ointment.

Synovectomy, arthrectomy, or joint erasion, resection and amputation, are exceptionally, if ever, justifiable in children. The frequency of recurrence *in situ*, the development of general tuberculosis and the sudden appearance of meningitis or phthisis when there is every reason for believing the brain and lungs were previously healthy, are sufficient cause to justify the belief that the traumatism of the operation and opening up of fresh channels of infection, where complete sterilization is impossible as in acetabular disease of the hip, more than counterbalance any possible good of the procedure.

As regards general treatment, tonics such as cod-liver oil, sirup of the iodide of iron, maltine, cream and fats are distinctly useful as in the expression of the tubercular diathesis elsewhere. Pure air, sunlight, a dry climate and removal to the seaside or mountains, where this is possible, are measures of the utmost importance. Creosote or guiacol internally appears in some cases to exercise some specific curative effect. Guiacol, the desirable principle of creosote, is usually unirritating to the stomach and may be given in doses of two to five drops three times a day. If the drug act favorably the nutrition and body-weight increase and an improvement in joint symptoms may be observed. Tuberculin of which so much was hoped has proved a failure save for purposes of diagnosis.

In conclusion, the points which I have desired to emphasize may be summarized as follows: 1. Both on theoretical and clinical grounds, treatment for children should differ from that appropriate in adults. 2. Conservative methods are usually successful and their trial is to be persisted in longer in children. 3. Relief from weight-bearing is as much indicated for the knee and ankle as for the hip where destructive disease is present. 4. Braces of untempered steel are preferable to plaster and its substitutes especially where abscesses complicate joint-disease. 5. Excepting when near joints or causing injurious pressure tuberculous abscesses should not be opened. 6. Radical operations are seldom if ever necessary in children.

145 West Sixty-sixth Street.

A Defence of the Dude.—The editor of the *National Medical Review* is moved to speak words of praise of the dude, who has the merit, he says, of cleanliness, for "his collar is not melted with the heat of many summers; neither are his shoes covered with the sands of time. His linen is not stained with the drippings of a tobacco press; neither are his teeth covered with the green algæ of antiquity. His face is not the sign of a poor barber; neither are his fingers ploughed with the deep fissures of the bichloride. The dude is surgically clean. Tubercle bacilli slip from his polished footwear; and the Klebs-Loeffler cannot find a nesting-place beneath his nails. He is the latest teacher; and wise are those who profit by his lessons." The editor is not complimentary to his professional brethren in Washington. In our favored city the above description applies with special fitness to the physician.

The Pennsylvania State Medical Society will hold its next annual meeting at Chambersburg, on May 21 to 24, 1895. It is requested that those members who intend to read papers will send the titles of the same to Dr. Dulles, 4101 Walnut Street, Philadelphia; and it is also urgently requested that those who are preparing papers will make them as brief as possible, so that all may have time to present their communications.

A CASE OF UNRECOGNIZED TUMOR OF THE CENTRUM OVALE IN WHICH TREPHINING WAS DONE FOR THE RELIEF OF INTRA-CRANIAL PRESSURE.[1]

By THEODORE DILLER, M.D.,
VISITING PHYSICIAN TO ST. FRANCIS HOSPITAL, PITTSBURG,
AND
J. J. BUCHANAN, M.D.,
SURGEON TO MERCY HOSPITAL, PITTSBURG.

It is well known that brain tumors may produce no symptoms, or symptoms which are inadequate upon which to base a diagnosis. Meredith[2] has reported a case (for a time under the observation of one of us) in which a woman, aged forty-four, had, for years, attacks which were in every way akin to those of essential epilepsy, in which the post-mortem revealed a small tumor in a cyst with extensive softening of the operculum on left side, where it was situated. Trowbridge[3] reports the case of a man, who at the age of thirty-seven began to suffer from seizures which for thirteen years were thought to be those of ordinary epilepsy. The autopsy revealed a tumor the size of a hickory-nut in the anterior part of the temporal convolution with softening of other two convolutions. In Knapp's[4] recent work may be found references to many cases in which brain tumors were discovered only on the post-mortem table. It is not our purpose in the present paper to make studies from the literature of the subject, but simply to report the following case and endeavor to ascertain, if possible, the lessons it teaches. We have, however, referred to the cases of Meredith and Trowbridge because they were in many ways similar to our own, and with ours seem to suggest certain lines of inquiry which will be referred to later.

History of Case by Dr. Diller.—M. K—— (seen for first time March, 1893), aged forty years; married; mill-worker; strong, powerful man. Seventeen years ago had a primary sore, followed by a breaking out on the body and a sore throat. Two years ago, for the first time in his life, he was seized with a fit. Since then they have frequently recurred. He has from one to six in a week. While taking medicine he was for five weeks free from attacks (the longest period of exemption he enjoyed). These fits are characterized by loss of consciousness, during which there is violent non-purposeful contraction of muscles of brief duration. He frequently bites his tongue. At first his seizures were all of this character, but soon he began to have light attacks, consisting of a "queer sensation" all over his body, with nausea and a feeling of weakness. A year ago had some twitching in the left arm and leg between the fits. A fit itself is never preceded by this twitching, which appears to be an independent phenomenon. This twitching was never strong enough to visibly move arm or leg. A month ago he had, for a time, some similar twitching of left face—probably only fibrillary twitchings. For three or four months past has noticed complete paralysis in right arm for about a minute following each fit. Part of this time he was troubled with headaches, but is not now. He was placed upon iodide and bromide of potash and acetanilid.

While he was under my observation (a year and a half) I examined him frequently to ascertain, if possiple, some data upon which to localize a focus of irritation. I often questioned him as to the character of his spells. Many of them were of the type ordinarily seen in essential epilepsy. Light ones were apparently of the *petit mal* variety. They occurred frequently in spite of treatment. Besides these apparently ordinary attacks of *grand* and *petit mal*, there were others which I note.

[3] Journal of Nervous and Mental Diseases, April, 1891.
[4] P. C. Knapp: Intra-cranial Growths.

April 24, 1893.—Fit while at table last Wednesday. Temporarily paralyzed in right arm. Could not speak for one minute. Consciousness preserved throughout the attack.

September 23d.—Light spell, in which he was momentarily paralyzed in right arm. Often has headache before a fit.

October 11th.—Three spells since the first of the month, in all of which he was conscious. Right arm powerless from three to five minutes. Headache preceded these attacks.

October 30th.—Five spells since last note. In two of these he had loss of speech and paralysis of right arm, lasting about one minute. Consciousness was not lost, nor were there convulsive movements of any sort. He is taking 3 j. of iodide three times a day.

November 9th.—Five spells last week, similar to others. Paralysis of right arm and loss of power to utter words for a minute or two.

November 11th.—Dr. Willets reports eye-grounds normal.

November 18th.—Spell every day last two weeks as noted above.

December 1st.—Sent to Mercy Hospital. Potassium iodide in one-hundred-grain doses ordered.

After a stay of several weeks he left the hospital and was lost sight of until September, 1894, when he again came under the observation of Dr. Buchanan. At this time he was taken with a series of convulsions, followed by alarming state of coma lasting three days.

An operation of some sort seemed to be demanded as a *dernier ressort* while he was in this state of coma. He came out of it, however, but was appreciably more stupid. Although we were unable to localize a growth or focus of irritation we decided to advise trephining, in the hope of bringing about some favorable change through relieving in some measure intra-cranial pressure. The man had for a long time craved an operation and at once consented when it was finally proposed to him. The frequent attacks which he had had during which the right arm was paralyzed and speech temporarily lost, while consciousness was preserved could perhaps scarcely be regarded as Jacksonian in type. Yet they differed from attacks of *petit mal* from which he suffered, and indeed from the ordinary types of *petit mal*. But as these were the only symptoms which appeared to have any localizing value (if, indeed, they had), it was determined to trephine over the arm centre on the left side.

Operation by Dr. Buchanan.—Operation, September 26, 1894. Chloroform anæsthesia. A large flap of the soft parts was turned down on the left side and a Roberts trephine with a diameter of one and a quarter inch was applied with its centre over the arm centre. This opening was enlarged with the rongeur forceps both ways in the direction of the fissure of Rolando. The dura mater was apparently normal, but a flap of it was raised and it was thought to be slightly thickened. The subdural space was explored in every direction with a blunt needle and with the finger, but it and the brain beneath were apparently normal in all respects. The dural flap was sutured with catgut and the scalp with silkworm-gut. The elastic band was used to control hemorrhage from the scalp and the usual antiseptic precautions observed. No drainage was made. The wound healed under one dressing, with practically no elevation of temperature. The operation had no apparent effect on his mental or physical condition, except that he was free from convulsions for about a week or ten days. He was in his usual condition during the day of October 24th, had a severe convulsion at seven o'clock in the evening, and died the same night.

The autopsy was performed by Dr. H. A. Royster, resident physician at the Mercy Hospital, who furnishes the following report:

Brain above average size, weight not determined. Convolutions well marked. Thickening of membranes

at site of trephine wound ; cerebrum beneath this normal. Sections horizontally through ventricles showed an excess of fluid and congestion of blood-vessels in ventricular walls. White matter of brain softer than normal.

The point of especial interest was a morbid growth discovered in the centrum ovale of the right hemisphere, situated about midway from before backward, and nearer the base than the vertex. This growth was about the size of a hen's egg, irregular in shape, not circumscribed, but encapsulated. It was darker in color and harder than the surrounding white substance which was distinctly pulpy. It presented numerous branchings and was enucleated with difficulty. Unfortunately, the specimen was misplaced, hence no microscopic examination was made.

The case is of interest from the problems it presented both in diagnosis and treatment. At first the symptoms were those only of essential epilepsy, although the history of chancre and the fact that the fits did not begin until the patient was thirty-eight years of age, naturally led us to suspect syphilis as the underlying cause of the symptoms, or, at least, as a contributing factor.

He was given a thorough course of anti-syphilitic treatment, but apparently without effect. An attempt was made to interpret the significance of the attacks he suffered from latterly in which his right arm was paralyzed and his speech lost temporarily. Unfortunately none of these attacks were observed by either of us. But the patient himself always described them in about the same way. In the absence of alterations in his eye-grounds, severe or persistent headaches, convulsive movements, vomiting, permanent palsy, there were certainly not sufficient data upon which to base a diagnosis of brain tumor. Indeed in view of his previous attacks of *grand* and *petit mal* it was questionable whether the momentary attacks of right-arm palsy were not those of *petit mal*.

But the facts that consciousness was preserved throughout them and especially that there was temporary aphasia cotemporary with this palsy, did seem to indicate that the symptom might be of some localizing value.

The supervention of coma forced the conclusion upon us that some grave organic, intra-cranial trouble was present. Trephining, as already stated, was advised in the hope that relief of intra-cranial pressure might in some way effect a favorable change. This we would have deemed advisable even had there been no localizing indications. But the arm and speech centres on the left side, apparently standing in some causal relation to his transient attacks of aphasia and monoplegia, determined us to trephine over the arm centre on left side.

The revelation made at the autopsy came as a great surprise to us. Dr. Royster, who performed the autopsy, says that he is sure that no error was made in noting the growth as being on the right side. So nothing was discovered which would account for the attacks of aphasia and right-arm palsy (unless they be explained by the thickened membrane), whereas there was present abundant cause to account for left-sided symptoms (which were not present). We are totally at a loss to offer, even in the light of the autopsy, a satisfactory explanation of the symptoms.

Cases like this and like those of Meredith and Trowbridge, already referred to, teach the lesson which has so often been taught before, and to which one of us has called attention in a previous monograph,[1] viz., that epilepsy, even so-called essential epilepsy, is only a symptom or a train of symptoms. It teaches, like Trowbridge and Meredith's cases, and many others, that extensive growths or softening in the brain may produce inadequate localizing symptoms or none at all. The theory of compensatory action or bi-lateral representation alone can account for the preservation of function of a part when the cortical organ is destroyed or cut off from the part which it represents.

The study of this case and similar ones teaches that we should ever be on the look-out for gross organic lesions in so-called essential epilepsy.

The weight of professional opinion is against operations in essential epilepsy save when there is some special indication, such as depressed bone, etc. Experience does seem to show that a large number of operations in these cases produce no beneficial effects. But we submit that in cases of so-called or apparent essential epilepsy, when large increase in frequency of fits takes place ; when coma, signs of intra-cranial pressure, or other evidence presents itself, auguring a sudden or a certainly fatal end, the operation of trephining, even in the absence of localizing symptoms, is not only justifiable but demanded.

This question was dealt with (and very ably) at the recent meeting of the British Medico-Psychological Association, held last June in Dublin,[1] in papers read by Dr. T. Claye Shaw ("On Brain Pressure and Trephining") and Mr. John Macpherson ("On Cerebral Pressure"), and in the discussion by Mr. W. T. Stoker, Dr. Mercier, Professor Benedikt, Mr. Swanzy, and Dr. George Robertson, which followed the reading of the papers.

Dr. Shaw, in speaking of the operation in general paralysis, says : "This much may be said for the operation — that it seems harmless when carefully performed, no fatal results having, so far as I am aware, ever resulted. The apprehended after-results, as regards local tenderness, liability to injury at the trephined spot, bulging of contents of the cranium, are phantoms which have no basis of fact. I fear, indeed, that we have not been bold enough in our measures. Mr. Harrison Cripps, who performed earlier operations for me, recommends removal of a much larger extent of bone ; of a piece, indeed, about three inches square, and he would do it on both sides of the skull."

Mr. Macpherson, writing "On Cerebral Pressure," says : "I do unhesitatingly maintain that many cases manifesting such a combination of symptoms as I have enumerated have derived undoubted benefit from surgical operations."

The discussion following the reading of these papers was opened by Mr. W. Thornley Stoker, President of the Royal College of Surgeons, Ireland, who used this emphatic language : "In any case where there is pressure the operation of trephining is a logical and a justifiable procedure. I feel very strongly upon this point. The operation is one that is in most cases practically free from danger. . . ."

Mr. Swanzy said, "It is a very desirable measure, *apart from any intention to remove the tumor*.[2] It not only seems to lengthen the life of the patient, but to preserve a much longer possession of sight than could be expected otherwise."

Dr. George M. Robertson, after presenting the other side of the question remarked as follows : "It must not be concluded from my remarks that I am opposed to these surgical operations ; I have merely stated that surgical interference in most cases is not justified. The operation is quite experimental ; *but there is full justification when performed in cases which would otherwise be hopeless*,[3] as it is simple and not dangerous."

Dr. Robertson was speaking of the operation more especially in general paralysis of the insane.

It will be seen that in these expressions of opinion our proposition receives material support. It is surely better to give a man even a small chance of improvement or extension of life than to give him none at all.

SCORBUTUS IN INFANCY.

By JOHN C. WISE, M.D.,
SURGEON UNITED STATES ARMY.

Despite the labors of Northrup and Starr in this country, of Railton, Sutherland, and Green in England, in establishing the existence of infantile scorbutus, it is to be feared that the profession at large, in America at least, have failed to recognize and utilize their demonstrations. No doubt this state of affairs is in great measure due to the indefinite ideas which we have of the pathology of the disease, as well as that of rachitis, with which it is so commonly confounded.

It is the object of this paper briefly to advert to the well-established fact, of the not uncommon occurrence of scorbutus in infancy and childhood, to emphasize the clinical features which assure the diagnosis, and to note the excellent success attained by the use of anti-scorbutic treatment. The phenomena of rachitis and scorbutus often coexist, and this we easily understand, both conditions being essentially due to malnutrition, and when our knowledge of biological chemistry is more perfect we shall doubtless find that but slight variation in developmental processes determine the one or the other affection. Scorbutus is looked upon too much as an essentially marine disease, peculiar to long voyages and polar expeditions; yet the profession must be familiar with the dire results caused by it among the forces of the allies during the Crimean War and the last siege of Paris. It is a common occurrence in Ireland, following failures in the potato crop; indeed it is quite true that while the applications of modern science in enabling ships to make rapid transits over great oceans and giving the ship's company an abundant and varied dietary, has banished scorbutus from the sea, it seems probable that the failure of American mothers to nurse their infants, and the introduction of proprietary foods, is destined to make scorbutus a formidable disease on land, under prevailing economic conditions.

If clinical and therapeutic arguments are not sufficient of themselves (as we contend that they are) to establish the existence of scorbutus in the infant, the significant demonstrations of "post-mortem" reports are most conclusive. The most important feature in this connection is the hemorrhagic results of scorbutus, a condition long well known, it is true, but found now so invariably in cases under dispute, proving the scorbutic character of the disease, even when blended with rachitis, as it undoubtedly often is.

In a case of Dr. Stephen McKenzie extensive endosteal and sub-periosteal hemorrhage was found to exist, but no evidence of rachitic conditions; other observers have noted hemorrhage into the dura mater, lymphatics, intestines, and pyramidal structures of the kidneys, while a most common occurrence during life is sub-periosteal hemorrhage into the orbital cavity. This hemorrhagic tendency, or diathesis, if we can correctly term it so, is the essential differential between scorbutus and rachitis, though we are aware of scorbutic conditions which have not run on to the hemorrhagic stage.

Without entering further into the pathology and "post-mortem" changes found in scorbutus, for which the profession is so much indebted to those I have mentioned, and more recently, Barlow, of England, I wish to call attention to the clinical phenomena which will most assist us in establishing the existence of the scorbutic state.

All practitioners are aware of the serious digestive disorders attending rachitis, the capricious and fagged appetite, the persistent diarrhœa, the foul-smelling and ill-conditioned stools. In scorbutus we have not this train of symptoms, and their absence in any case of suspected rachitis should lead to great care in establishing the true nature of the malady; indeed, if the little sufferer has not been heroically treated with cod-liver oil, sirup of iron, and hypophosphites, capable in themselves of seriously deranging the digestion, it will often take food in greater quantity, in the vain effort to supply the necessary elements of growth. Still more characteristic is the state of the gums, and this will depend in great measure on the progress of dentition. If no teeth have erupted there may be nothing amiss beyond swelling and turgescence of the gums. Coincident with the eruption of the teeth the gums become swollen and spongy, fleshy growths form, often of considerable length, sometimes covering the teeth, which thus appear to have receded; they are the seat of frequent bleeding, which adds to the fetid odor of the breath; as to rachitis, the teeth are dark or black, and corrugated.

If the true character of the disease is not suspected we will probably be asked to treat a catarrhal conjunctivitis, which will prove unamenable to the usual treatment—the lids puff and swell, the eyes protrude, and give a distorted appearance to the visage; sooner or later we will notice an ecchymosis about the palpebræ, usually the upper, all of which is the result of hemorrhage into the orbit. This state of proptosis with ecchymosis is usually persistent.

As in the acute stage of rachitis, we have moderate elevation of temperature, with dryness of the lips, but sweating is confined more to the head and chest. Coincident with these symptoms we have the marked hyperæsthesia, the pseudo-paralysis, and the bone lesions of rachitis, but such symptoms as craniotabes, and the "rachitic rasures" are absent, which is an important fact, as we are aware that changes in the chondro-sternal articulations are the earliest osseous changes in rachitic disease.

If the pathological results, demonstrated post-mortem, and the widely divergent clinical course, were insufficient to establish the existence of scorbutus in infancy and childhood, we must regard the result of these therapeutical applications as conclusive. In the entire field of medicine there is no such immediate and happy results obtained as from the exhibition of anti-scorbutic treatment in these cases. We find a most decided "désagrément" of many parents of rachitic infants to be a feeling that the occurrence of such disease is a reflection, inasmuch as its more common abode is in the unhygienic homes of the poor, associated with lack of food and care, and while this is in great measure undoubtedly true, we do not find the etiology of scorbutus to correspond.

On the other hand, scorbutus, as occurring in young subjects, is agreed to occur more commonly in the homes of those who are in comfortable circumstances. It is explained by the fact that while the diet of the infants of the poorer class is not what it should be in its variety, it approaches more closely that demanded by nature than the expensive proprietary articles used by wealthier parents. And this is undoubtedly true. In my own observation there has been such uniformly good results following the abandonment of the proprietary article and the substitution of cow's milk, that I consider the former not only negatively but positively prejudicial to anything like normal development. And if the mammary glands of women are to be relegated to the artists, we may at least hope that those of the cow may be their humble, but useful, substitute.

Just what is wanting in a dietary to cause scorbutus, physiological chemistry does not inform us. It is neither the citric, malic, or tartaric acid, nor the alkaline bases, nor yet their combination, but we are aware that as existing in lemon and orange juice, and that of fresh vegetables, blended as nature intended, they only are efficient.

It would seem eminently wise to distrust the elaborate and complex food-products which crowd the market, and in shaping a dietary for infants adhere as closely as possible to simpler forms of food. Otherwise we may destroy a principle, it may be, of no greater

fruity than the bouquet of a wine, due to a volatile ether, yet the loss of which radically impairs the value of the article for nutrient purposes.

In conclusion, I will briefly cite a case of infantile scorbutus, as illustrative of the differences noted and as diagnostic of this disease.

S. M——, aged thirteen months, of healthy parentage, in comfortable circumstances, came under my care in October, 1893. The child had been fed soon after birth on artificial food. He had been a bad sleeper, was quite pale, and evidently not well nourished. While passing the summer of 1894 in Massachusetts, serious symptoms of malnutrition occurred; it had been standing and trying its limbs; now voluntary movements ceased, cheerfulness was lost, to be replaced by various manifestations of malaise and pain. The lower limbs remained flexed and helpless; extension gave great pain. There was also commencing swelling of the wrists and ankles. The disease was pronounced, in Boston, to be rachitic, and a treatment of cod-liver oil, lime, and the sirup of hypophosphites ordered. When seen in October, 1894, the symptoms were more decided; the limbs hung in a helpless way, or were flexed when recumbent; the ankles and wrists were considerably enlarged, with great general tenderness; temperature ranging from one to two degrees above normal. Appetite good, digestion fairly well performed. No diarrhœa, but stools of bad odor and color. Decided sweating of the head and upper extremities. Two upper incisors had erupted, were black and furrowed; the gums, though swollen and inclined to bleed, were not characteristic of scorbutus. In November, a hemorrhage had occurred into the orbit, the eye protruded forward and downward. The bone changes had advanced rapidly; the right thigh was swollen and extremely painful in its entire length. At a consultation held some two weeks prior to this time, cow's milk had been ordered more liberally, and beef-juice as an additional article of diet. The sirup of the iodide of iron in large doses was well borne. By December 1st, the infant was decidedly worse; the gums were the seat of fleshy growths, easily bleeding; the breath was so impure as to require frequent antiseptic washes. Loss of flesh had been continuous, and it was evident that without radical change there was no hope for it. The diet was made pure cow's milk, with usual addition of lime-water; to the milk was also added sieved potato, and sweet oranges allowed. In two weeks' time a great change for the better was obtained in every respect—the swelling slowly subsided, the gums became firmer, the teeth whitened, and voluntary movement was resumed, so that at Christmas the little sufferer was practically restored to health.

Navy Yard, Washington, D.C., January, 1895.

The Physician to the Family of the Ameer of Afghanistan is Miss L. Hamilton, formerly of Sundrum, in Ayrshire. She was trained as a nurse in the Liverpool Infirmary, and afterward studied medicine, taking the degree of M.D. in Brussels, three years ago. She went to India and was practising in Calcutta, when the Ameer offered her a position at a good salary in Cabul. She accepted his offer, against the advice of the Indian authorities, who told her they could not guarantee her protection from insult or injury if she went to live among the Afghans.

The Sale of Patent Medicines is said to have increased immensely in this country during the past year, the sales of some favorite medicines having been five, or even ten, times as great as in any previous year. This is one of the common phenomena of periods of financial crisis, those who are slightly ailing preferring to take their chances with cheap patent medicines rather than to consult a physician and pay his fee.

NEURASTHENIA—ITS CURE BY THERMO-THERAPY.

By G. MANLEY RANSOM, M.D.,

NEW YORK.

Are the organic causes of neurasthenia known? What are the physiological influences in this disease that thus tend to alter the general tone of the individual, of his intellectual and emotional faculties, of his total sensibility? Is there some condition of the circulation, general or local, or some inhibitory action, some arrest of function?

These fundamental questions can be satisfactorily answered though a proper study of human physiology. Valuable hints regarding the physiology of the vasomotor system have been obtained from experiments on the lower animals, and to some extent from pathology, and these have stimulated investigations in regard to augmenting and inhibiting actions of nerves on the vascular system. Those of Angel, Moso, Webber, and others, seem to show that an unstable vascular tone, or irregularities in the vasomotor system, due probably to over-excitation of the central nervous system, and whence results extreme irritability of the vacular system, account best for the symptoms of neurasthenia.

From these experiments it seems very probable that in this disorder the brain symptoms, and also those relating to organs of the body, are due to contraction of the small blood-vessels, causing ischæmia in certain regions, with consequent insufficient nutrition and exhaustion. But this probability may be said to be reduced to a certainty when, through the effects of temperature alterations on the skin in equalizing the circulation, neurasthenia can be cured.

That treating neurasthenia by "thermo-therapy" gives us the full facts of this disease, and not an abstraction, becomes apparent when it is seen that, by a single proper treatment of this kind, we can rapidly relieve all the indicative phenomena of this disorder.

When a neurasthenic patient, immediately after such a treatment, who has been miserable and complaining just before it, invariably feels better, and almost always volunteers this information, and at the same moment his pulse-tracings and other objective symptoms, show that his circulation has improved, that since the treatment it is nearly or quite normal; and when, after a series of such treatments thus tending to promote the progressive co-ordination of his vascular actions, his circulation becomes permanently normal, and he declares himself well, is there any further evidence necessary as to the nature of the physiological causes of this disease?

Studying vascular actions in the lower animals, can give us merely an abstract of such functions in these animals. This can assist to a knowledge of physiology, but certainly it cannot be made directly to give us a true knowledge of correlated physical and psychic states as thermo-therapy can.

None of our nervous apparatus is an abstract unity, there is no such thing as a sense-apparatus or a motor-apparatus in general, as they are described for convenience in physiological treatises, but only a concrete individual apparatus, the study of which as a dynamic whole, can alone satisfactorily explain the general state—the psycho-physiological state of the man.

We cannot picture to ourselves the general sensibility as separated from the higher sensibilities in any fully conscious state, or primary reflex actions, as unconnected with the highest forms of these actions within us. That we know ourselves through the consensus of our sensibilities, is proved by the effect of temperature variations in altering states of our consciousness; for example, in this case Dr. W——, a practising physician, of Burlington, Io., who was miserable and complaining before a proper thermal treatment, and who expressed a feeling of relief and well-

being immediately after such treatments. He sends me the following letter:

"When I came to you, on my way south, I was suffering from neurasthenia, with all the distressing symptoms that make the life of the neurasthenic miserable—insomnia, occipital headache, neuralgias, mental depression, and inability to mental concentration without great fatigue, with an irritable heart, and constant apprehension of impending evil. Your first treatment with the douche brought me some relief, after the second I had no trouble about sleeping; now, after eight treatments, I feel well, none of the symptoms above enumerated bother me. Have a general feeling of well-being and elasticity. I feel that the benefit I have so happily derived from these treatments is chiefly due to the care and good judgment with which they were administered. I find that I have gained one pound and a half in weight. With this turn toward health I am confident that a rest, and the benefit of an out-of-door life for a time, will completely restore me. I leave for Florida to-morrow."

Another case, a prominent Western manufacturer, aged fifty-four, came to me October 12, 1894, from Dr. Bache McE. Emmet of this city. This patient had tried baths of various description, and electricity, without relief from either insomnia or pain, and was very dubious about such treatments affording him help. For five years he had spent over half of each year in travelling to the different springs and health-resorts without being benefited. I quote from his letter to me, September 10, 1894: "I have tried baths, half packs, full packs, salt rub, and douche, also electro-thermal and chemical baths, static electricity and massage, without either relief from pain or increase of sleep." Another part of his history may be given with precision in his own language. Having first mentioned a visit to Boston, in January, 1890, to consult a specialist, who called in several others in consultation, sending to New York for one, he writes: "Decision was, trouble caused by some serious stomach trouble. I was sent home as the best place. Home doctors claimed it was nerve trouble, or prostration from overwork, which was my own belief, as I had been troubled with insomnia for years, sleeping but a few minutes at a time, and then only latter part of night; but they treated me on the line of the Boston conclusion, viz., diet and constant use of hypodermic syringe, as required for severe pain. Stomach got better, but nervousness and pain continued as at first whenever syringe was not used. This has lasted for five years, during two years of which I had comparatively no stomach distress. I was eating liberally of anything except very rich food, in fact I often remarked I did not know I had a stomach, as far as distress was concerned. The past two years nervousness, pains in the breast, spine, and under the shoulder-blades had been getting much worse, until in August, I found I would soon be insane from the frequency of the pain and inability to sleep. Was only relieved by syringe until nearly ten times the original quantity of morphine in twenty-four hours was used, and without relief except for very short intervals, two or three hours. Strength fast going, confined to bed most of September and first half of October."

The record of this patient, kept for Dr. Emmet, contains many figures relating to hours, medicine taken, and decreasing doses of morphine. I shall therefore merely quote some concluding remarks: "Came to New York by Dr. Emmet's advice to try treatment with the douche. First treatment October 12, 1894. Second week much better and have gained four pounds, third week gained two pounds, much stronger, with somewhat better nights. Since that time have gained in strength, no loss of weight, can walk a mile without fatigue and sleep comparatively well. Acute pains have almost disappeared, nervousness not near so marked, and I can feel improvement steadily by the week with an occasional set-back for a day only, and morphine reduced to one twenty-fourth of a grain, taken at long intervals."

Mr. G—— has gone to his home to spend the holidays. We do not consider him cured, but his case has been so much benefited by this treatment, where everything else had failed, that he will continue it as long as necessary. I should like to say that, although he had been treated before by douches, as he states, they were administered in such a way that the shock confined him to bed, producing lasting bad effects. In treating this case I chose the douche because of the facility with which, by its use, temperatures and pressures can be rapidly and accurately varied to meet the requirements of the most delicate states and parts of the body. A letter just received from the patient about his return, dated December 31st, says: "I have held my own, and have been congratulated by every one on my improved appearance."

Dr. W——, New York City, came to me May 2, 1894. This patient's prominent neurasthenic symptoms were insomnia, indisposition, depression, night-sweats, apprehension, loss of weight, down-heartedness. It was only by the exercise of unusually strong will-power that he had been able to continue his professional duties. I treated him steadily with vapor baths, being guided by his pulse and sensations in regard to the temperature and duration of baths. This treatment was continued until July 5th, at which time Dr. W—— was considerably improved, and I left the city. He returned to me on October 29th, having remained in the city, and at work, all summer, which brought back all the old symptoms, with even more mental depression. I began treating him daily, alternating douches with vapor baths, sometimes combining them, the temperature being varied to meet the indications of his pulse and changing sensibility. At first, before the treatments, his pulse varied between 100 and 110; After a full reaction from these treatments between 90 and 85. It is now, except occasionally, normal, and he has gained twelve pounds in weight since October 29th—altogether twenty pounds since May 2d. He now eats well, sleeps well, and is much interested in some scientific work that he has undertaken in addition to his regular professional duties. His present enthusiasm and energy are in marked contrast to his condition when he came to me two months ago, downhearted and talking of giving up his practice, at a great sacrifice, for a long rest.

Mr. C——, thirty-five years of age, sent to me by Dr. H. F. Walker, of this city, September 12, 1894, for douches. Although of fine physique he became easily fatigued, mentally and physically, and was much disturbed about a numbness that attacked his arms and legs at times, and the undue mental confusion that any business question brought on. After the second douche he thought he "felt a difference." As they proceeded he reported a steady improvement, which was more noticeable on the day following the treatments. He is now, after twelve douches, able to decide questions that arise in the management of his affairs without the hesitancy and confusion that had so distressed him. The numbness has also disappeared, and his full physical strength has returned.

Miss H——, referred to me by Dr. A. H. Smith, of this city, October 25, 1893, was neurasthenic, had received a shock in a railroad accident some two years before, since which time she had suffered with pain in the back and head and general debility. She was unable to take any exercise without fatigue and pain. Her first visits necessitated a carriage and pillows, assistance in going up and down stairs and in dressing, very marked hyperæsthesia over the dorsal region of the spine. She was treated with very mild warm spinal douches, and very carefully administered light massage daily as the treatment best adapted to her weak condition. She gained steadily in strength, and when she returned to her home, early in December, she had been to church

and to the opera, and could walk to and from her hotel, a distance of three blocks, unassisted. She was much cheered mentally, as since her accident she had been forced into the *rôle* of a confirmed invalid, not even being able to participate in entertainments in her own home. Miss H——, while being treated by me, was under the constant observation and care of her physician, Dr. Smith, and it is by his courtesy that I describe her case. This cure has been permanent.

Mrs. B——, Bridgeport, Conn, came to me December 20, 1892, having been a confirmed neurasthenic for five years. I treated her for two weeks with warm douches and massage. She returned to her home, for the holidays, improved, and early in January again placed herself in my care. She remained here nine weeks, steadily gaining in strength and mental tone. As she was suffering from the effects of a lacerated cervix, I performed hystero-trachelorrhaphy, assisted by Dr. J. F. McKernon, of this city. I will quote from her husband's letter two months later: "At the time my wife went under your care she had received treatment at the hands of several specialists, and with little or no beneficial results to her nervous system. I feared she had become a confirmed invalid, and organized my household accordingly. It is now a little more than two months since she left you. Gradually she has assumed her family cares and responsibilities. She seems now quite like her former self, and has dispensed with the housekeeper."

Mrs. H——, sent to me by Dr. C. L. Dana, of New York City, February 4, 1892, suffering from neurasthenia of two years' duration. Symptoms: Almost constant headache, insomnia, neuralgias, and mental and physical inability. For four months before Dr. Dana treated her she had been entirely dependent on drugs for sleep and relief from pain. Baths he prescribed resulted in a prompt amelioration of all the above symptoms. She improved steadily, until after twenty-four baths she considered herself "better than for years." When in New York, a short time ago, she came to tell me that her improvement had been permanent. Space does not allow my reporting many more cases, the data for which are available, relating to the cure of neurasthenic doctors and other patients by thermo-therapy.

In these cases the treatment was regulated to consist with the condition of the pulse and the varying sensibilities of the patient, who was comfortable during and after each treatment, although the temperature was sometimes varied from 8° to 15° F., or more, all shock was carefully avoided. The room temperature was also regulated to suit each patient when naked. My experience in treating several hundred cases of neurasthenia with baths convinces me that they will not stand shocking. This is contrary to the apparent purport of most text-books on hydrotherapy, and for this reason I consider it of the greatest importance to call the attention of the medical profession to it, and more particularly as the cold bath is so commonly prescribed in neurasthenia. They seem to react well, and report that they "feel fine," after it, but this effect is transitory and nearly always at the cost of too great nerve expenditure. Nutrition does not always make up the loss, and in the end this treatment is a strain on the nervous system. It is good to exalt the nervous system moderately, whereby we may produce the normal degree of functional hyperæmia, which, as above shown, is absent in this disorder, but when an asthenic patient says he feels "fine," "splendid," or "deliciously," after a cold bath, he has probably been too highly stimulated and at a later hour will feel depressed in consequence, although he will not usually attribute this result to a bath which has given him such relief. His physician, be it regretfully said, will too commonly, when these conditions exist, fall into the error of recommending still colder baths, following hydropathic instructions perhaps, or what may be just as bad, will direct him to take, in addition, some unusual exercise which can but further exhaust his strength. Do not let us forget that we are dealing with nervous exhaustion and a delicate state of the organism. These patients should have baths carefully regulated to suit their constantly varying sensibility. If a cold bath is agreeable to a delicate patient he is an exception to the rule; but no matter how accustomed to cold baths he may have been in better health, as a neurasthenic he is peculiarly weak—important nerve-cells are not well nourished and you cannot re-establish their nutrition by violent shocks. By cold I mean now what is called cold in text-books on hydrotherapy, which seems approximately to be from 93° F. down to 40° F. Of course cold, as we know it, is relative heat, not absolute cold. The important fact we have to remember in thermal treatment is that the sense of heat will vary with the individual, and at different times in the same individual, and that therefore the real value of degrees of temperature in this treatment depends upon the state of the sensibility of the patient at the moment. The condition of the circulation is not always a safe guide to the immediate temperature requirements of the organism, though it does influence its reactions. Excessively irritable nerve-cells may react vigorously to a stimulus, but this does not prove that the waste following this activity will be promptly restored by nutrition, nor have we any reliable assurance from a temporarily normal circulation as to the capacity for resistance of these sensitive cells. The peripheral sensory nerves being abnormally irritable alters the reflex intensity of any stimulus applied to them. If, then, by artificial heat, or in any way, a degree of hyperæmia of the skin and a certain exalted condition of the pulse is induced in a delicate patient's case, if in this way "a sudden afflux of blood is brought to the skin, and the circulation both in the tisssues and nerve-endings becomes as active as that of a robust man after a vigorous exercise," and if at this moment we apply briefly to his naked body a temperature of 85° F., or some lower temperature said to be appropriate under these conditions, if, in a word, we follow carefully all the directions as laid down in books for a bath treatment of such a case, very likely a so-called good reaction will follow—the patient will feel exhilarated and his pulse and skin circulation may be up to the normal standard, but there is another reaction soon to follow, a relapse from this exalted condition must come, and then how far beneath the normal standard may this delicate patient's condition be depressed? Will he have recovered before the next treatment, and be in condition for a still higher degree of stimulation, as is sometimes recommended under these circumstances? Almost always a bath attendant, not a physician, attends to the carrying out of the details of such a bath. Were this not the case, were physicians to realize the great value to general medicine of a thorough understanding of this subject, then there would be less theorizing upon these baths by men who must have very little practical knowledge of them. I regret to have to speak in such an incidental way of such an important subject. Remember that the state of the sensibility is secondary to the organic state and indicative of it—of its requirements; that the objective phenomena of the local and general circulation have their greatest value as guides, when properly studied, with the total sensibility, and that the sum of the total sensibility as produced by a bath, may be known through the utterance of your patient at any moment after the beginning of his thermal treatment. Facts and experience abundantly show that each succeeding repetition of a temperature impression on a sensitive nerve-cell tends to alter it, and its association with other cells. The phenomena of habit are fully explained by this. A habit of co-ordination can be easily substituted in a simple functional disease. After a proper bath the neurasthenic patient will always experience a feeling of relief or of a moderate well-being. Such an effect from a single bath is in a degree transitory, but in it there has

been substituted a moderate impression of well-being for a general discomfort, and this is produced without excesssive nerve expenditure. In this condition the organic state of the patient has been changed, and there is consequently a new consciousness, subordinate to the new organic state, and this can be the beginning of a normal physical and mental habit.

Progress of Medical Science.

The Clinical Significance of Perigastric Adhesions.—According to the Paris correspondent of the *Lancet*, Professor Terrier, about a year ago, reported the case of a woman affected with intense pain in the epigastrium, due to the presence of adhesions binding the stomach to the neighboring organs. Laparotomy was performed, and the most careful examination failed to bring to light any other cause for the trouble than the existence of these adhesions, the rupture of which brought about a lasting recovery. Since then M. Terrier has had under his care a woman, aged fifty, in whom symptoms referable to the stomach had appeared ten years ago. These symptoms were dyspepsia, vomiting, and great pain. After a respite of two years the same trouble reappeared, accompanied with hæmatemesis. A second respite, lasting three years, was followed by a third attack, and a fourth attack occurring in October, in 1893, brought her in an emaciated state under the notice of M. Terrier. The epigastric region was doughy to the touch, and the stomach was dilated. Laparotomy brought to light a slight induration at the cardiac orifice and numerous adhesions between the stomach, the liver, and the omentum. The adhesions were divided, and the woman has remained well ever since. M. Championnière had under treatment three years ago a man who had suffered for twelve years from epigastric pains. The most contradictory diagnosis had been advanced to account for his trouble. Stoicesco, of Budapest, was the only surgeon who had suggested the existence of perigastric adhesions, the idea being based upon the fact that the seizures occurred one hour after meals, and reached a climax two hours later. Laparotomy was had recourse to by M. Championnière, and dense ligneous adhesions were discovered binding together the stomach, liver, and omentum. So hard were they that much difficulty was experienced in sectioning them. The only morbid antecedent that could in this case possibly account for the presence of the bands was an almost forgotten abscess of the liver which had emptied itself into the gut.

Pseudo-Paralysis Myasthenica.—At a recent meeting of the Berlin Medical Society, according to a correspondent of the *Medical Press*, Professor Jolly exhibited a case of this kind. He said the disease had of late been variously described, but not commonly known. The case was the second he had seen, the first had ended fatally. In the present one the condition permitted a more favorable prognosis. The boy, aged fourteen and a half years, was healthy until the commencement of the present illness. There was no nerve disease in the family. When aged one and a half year he had had fits that lasted some days, but never again. He had been quite strong, with good muscular development, and was an expert climber. The illness began in the summer of 1893. The first symptom was that the boy could not see the blackboard properly, as it was impossible to keep his eyes open long together. The eyelids fail after continued exertion. After rest and in the morning the weakness was not present, but came on again after continued looking. The next symptom was a tiredness of the legs, at first on mounting steps, but afterward on simple walking. In a short time he became so fatigued with walking that he would suddenly fall in the streets, but without loss of consciousness. Always after resting a short time he was able to walk on a number of steps further. Some months later the same symptoms appeared in the arms, and later on in the muscles of mastication and lips, so that at last the patient could not articulate. In the case first observed there was similar tiredness of the pharyngeal muscles. All the muscles were affected in the way that after a rest they performed their function, but after short activity lost their power, to become active again after rest. The ptosis, which at first had been so marked, was now present in much smaller degree, so that the boy could keep the eyes open for a quarter of an hour at a time. The tiredness in chewing was better, and in swallowing there was none at all, while in his first case the patient could not swallow after swallowing a few times, and died suddenly while eating. Electrical irritability appeared at first to be normal, but if the current were kept up somewhat longer, fatigue soon showed itself. The abnormality must be in the muscles themselves. There must be an alteration of the chemical condition on which the contraction depended. Some alkaloids were known that induced a similar condition, such as veratrine, physostigmine. As regarded the myasthenic condition, Professor Böhm, of Leipsic, had stated that it depended on a similar alkaloidal action, that of proto-veratrine. There must, therefore, be an abnormal condition in the muscles in these cases. There was the question also of the central nerve change, something similar to that described by Benedikt in 1868 as the "reaction of exhaustion." As regarded treatment, the muscles should be spared as much as possible, and when the patient could no longer swallow he should be fed by enemata. Electricity was said to be useful, and arsenic also, and there might be alkaloids that had an action antagonistic to the condition.

The Origin of Inflammations in the Urinary Tract.—According to Drs. Posner and Lewin, most purulent inflammations of the urinary organs are caused by micro-organisms introduced from without, in the majority of cases by means of a catheter. Instances, however, occur of severe cystitis and pyelonephritis where no such mode of infection is possible. The supposition has been hitherto that it might be derived from the intestinal canal, and it has been shown that the bacterium coli plays a considerable part. Experimentally, a superficial injury to the large colon has led to cystitis, pointing to a direct passage of bacteria from the intestine to the bladder. The authors endeavored to solve the question by closing up the anus and at the same time ligaturing the urethra. In all cases micro-organisms were found in the urine, while in stoppage of the urethra alone the secretion remained absolutely sterile. The organism found was almost always the same gas-forming bacillus belonging to the same group as the bacterium coli. The question, then, was whether the bacteria passed directly from the distended rectum into the bladder. The possibility of this occurring was present, as well-marked peritonitis has developed from an intestinal obstruction. Further investigation proved this event to be rare, for they found the bacterium coli not only within the bladder but in the kidneys as well, while the peritoneal fluid between the bladder and bowel was sterile. Posner and Lewin hold, therefore, that under favorable circumstances intestinal micro-organisms can be taken up by the blood and excreted through the kidneys—a process known to be present in certain infectious diseases. They proved this possibility by injecting cultures of the bacillus prodigiosus into the intestine and finding them in the bile, blood, kidneys, and urine. This would furnish an explanation of auto-infection from the intestinal canal showing itself, not only as an inflammatory affection of the genito-urinary tract, but also in other parts of the body.—*Berliner klinisch. Wochenschrift.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, March 23, 1895.

PROFESSIONAL RELATIONS WITH CRIMINAL ABORTION.

THE recent arrest of two regular physicians of this city on the nominal charge of accessories in a case of criminal abortion has justly aroused the profession to the danger that may attend a strict performance of duty under like circumstances.

The facts of the case are fully stated in the report of the proceedings of the Medical Society of the County of New York, which appear in another place. Briefly summarized, the points are these: A reputable physician was called to see a woman dying of septic peritonitis in the house of a midwife. The patient denied that any criminal operation had been performed and positively stated, to the best of her knowledge that the miscarriage of which the sepsis was the result was caused by a strain in lifting. The midwife stated that she had used only tampons to control the flooding. The gravity of the case made a consultation necessary. The consultant, after hearing the same story, proceeded to afford such counsel and assistance as seemed necessary, after which the patient was sent to a neighboring hospital. The hospital authorities promptly notified the police of the circumstances and the following morning the two physicians were taken into custody and escorted from their offices by two policemen to the police station. The attending physician was also taken to the hospital to be identified by the patient. The patient, however, was dead when the physician and policemen arrived. Before she died the patient charged the midwife with the abortion, but emphatically exonerated the two gentlemen who had endeavored to minister to her in her last extremity. In spite of this positive evidence, the physicians were taken to the police court, and thence, under the escort of two detectives, and in company with the midwife, were sent to the coroner's office. The coroner, taking an undue advantage of the situation, insisted upon imprisonment or bail, but was eventually persuaded by parties who were better able to understand the real merits of the case, to release the supposed culprits on their own cognizance. A coroner's jury of physicians subsequently entirely exonerated the attending physicians, but not until the suspicions of criminality against them were widely published by the daily press.

As almost any physician under like circumstances may be similarly treated, it becomes a matter of great importance to decide upon a course of conduct which shall guard the medical attendant on the one hand, and conform with the law on the other.

While it is well understood that no physician must violate the confidence of his patient, we believe that it is equally admitted that, in following out such a principle, he is not warranted in openly defying a law. In other words, it is not expected of him that he shall, even in a professional capacity, abet a crime. While he should not fear to perform his professional duty to the vilest sufferer who may need it, he is by no means called upon to be accountable for the circumstances which necessitated his services, particularly in such cases in which a suspicion of wrong-doing may attach to himself. While it is perfectly true that no reputable physician has been found guilty of producing abortion, it is nevertheless perfectly proper that he should use every means to be above even the suspicion of so doing. Thus it would seem to be his duty to protect himself under all suspicious circumstances. One of the latter is a call to the house of a midwife or an abortionist. The lesser evil of a reasonable doubt should, for his own protection, give way to the greater ones of danger to his practice and damage to his good name. He cannot, in complying with the letter of the law, afford to wait until his patient is dead before he divides his responsibilities with a proper official. Abortion is none the less a crime even if the patient lives; the only difference being that there is but one murder instead of two. In any and every event the physician in attendance should keep his own skirts clear.

A reasonable way of adjusting all apparent difficulties in a suspicious case would be to give information to a coroner, and preferably a medical coroner, who could then act with reasonable discretion, and assume the responsibility of obtaining the necessary evidence for conviction of crime, independent of any direct or unprofessional testimony from the physician himself. This would obviate entirely the report to the police, which so often ends in the escape of the real culprit and, as in the instance before us, in the shameful injury of innocent parties.

THE ABORTIVE TREATMENT OF COLDS.

ONE of the last of the many contributions to therapeutics made by the late Professor Dujardin-Beaumetz was an article on the abortive treatment of "colds," or more specifically, of acute bronchitis (*Bulletin général de Thérapeutique*, February 15, 1895).

The special and, in the author's opinion, almost specific, treatment of the "rhume," consists in the proper use of aconite. Dr. Beaumetz describes the varying tides in the popularity of this drug, and ascribes the changes to the fact that the preparations and strength differ as well as the reaction of the patient. For many years the French codex prescribed the tincture of the leaves, which is comparatively inert. In later times the root has been employed, and the results have been more satisfactory.

One disadvantage in the use of aconite lies, we are told, in the great difference in susceptibility to its effects. Every year, in France, deaths occur from the

use of aconite or its alkaloid, and Professor Brouardel is reported to have said he would never dare to use the drug. This is a condition of affairs quite different from that met in the United States, where aconite is used with the greatest freedom and is one of the mainstays of homœopathy, used in strong "mother tinctures." Bearing in mind the two disadvantages of aconite, its variability in strength and the idiosyncrasies of individuals toward it, Dr. Beaumetz still asserts that it is a most effective drug in acute bronchitis. He advises heroic doses, giving fifteen to twenty drops in a hot drink, and repeating this once or twice in the twenty-four hours. If much medication is applied at the beginning of an attack it will almost certainly abort it.

There is, however, a better method than this, viz., the giving of small and frequently repeated doses, as described by Ringer many years ago.

Another remedy which is very popular with the laity, is an ounce and a half of brandy in a hot infusion of violets.

The modern school inclines in the treatment of colds to use the coal-tar products, and ignores the old-fashioned teas, the antimonial and opiate powders of earlier times. But aconite, at least, will hold its place as a powerful help in the treatment of acute bronchitis and the so-called colds of the head and chest.

THE SPECIFIC TREATMENT OF TYPHOID FEVER.

A NUMBER of investigators are now engaged in the search after the curative toxin or antitoxin of typhoid fever, and from time to time certain somewhat encouraging results are published, although nothing positive has yet been obtained. Some of the more recent of these experiments were conducted by Professor Krauss, of Vienna, assisted by Dr. Buswell, of Buffalo. They were made with cultures of blue pus bacillus in bouillon, heated when three days old to a temperature of from 140° to 176° F. Subcutaneous injections of 7 minims of this sterilized culture were made on two successive days into guinea-pigs, and a week later the animals were inoculated with 45 minims of a virulent culture of the typhoid bacillus. None of these animals appeared to be injuriously affected by the typhoid injections, while those guinea-pigs inoculated at the same time, who had not received the preventive injection of the dead culture of bacillus pyocyaneus, died in about twelve hours. A trial of the dead culture was also made in the case of twelve men suffering from typhoid fever, two of whom died. In these two cases there were found ulcers partly cicatrized and also some patches of fresh infiltration, showing that the disease had progressed despite the employment of the remedy. In the cases that recovered there was nothing to indicate that the injections had materially modified the course of the disease. In three there was a distinct fall of temperature, generally transitory, after the first rise following the injections, but in others there was a successive appearance of spots of eruption during and after the employment of the injections, while the temperature curve was not affected. There were no untoward after-effects which could be attributed to the action of the remedy.

The results of these experiments were, on the whole, not particularly encouraging, despite the apparent antidotal action observed in the case of guinea-pigs. Certainly the time is not yet ripe for the introduction of the method into daily practice, though that the day will come when most cases of typhoid fever can be aborted or cured by the injection of some product of the specific bacillus (most probably an antitoxin) is within the range of probabilities—at least, one may now indulge in the hope of such a discovery without exposing himself to ridicule as a dreamer.

"ACADEMIES OF MEDICINE."

IT used to be considered sufficient to call a medical society simply a "Medical Society," prefacing the name of the locality or perhaps that of some distinguished physician. There is a tendency now to go a step further and call medical organizations "Academies." We note the creation of an Academy of Medicine in Chicago, Cincinnati, Cleveland, St. Joseph, Portland, and several other places. The "Academy" is, we believe, distinguished as a rule from the ordinary society by charging higher annual dues and by being a little more rigid in its requirements for admission. The name carries some dignity with it, and we trust and believe that these new societies will try and live up to their name. If there could be a law forbidding the creation of Academies of Medicine except under conditions calling for a high standard of scientific work and professional reputation, the increase and proliferation of these bodies would be an advantage. If, however, every local society begins to take upon itself a high-sounding name, while it is in fact a small and commonplace body, Academies of Medicine will soon become ridiculous.

We trust that a due sense of responsibility will always be felt among those who in the future organize and name themselves Academies. In the history of medicine, Academies of Medicine have always been composed of men of learning and experience, and their work has been of a high character. It would be unfortunate if the name became one of reproach.

Look to yourselves, therefore, Academicians, for what says Plautus, *Virtute ambire opportet, non nominibus*—or words to that effect.

PROPOSED DIVISION OF THE DEPARTMENT OF CHARITIES AND CORRECTION.

THE necessity for reforms in the conduct of New York's Department of Charities and Correction has often been referred to in the MEDICAL RECORD. We are pleased, therefore, to note the introduction by Assemblyman Pavey of a bill which, if it becomes a law, will prepare the way for much-needed reforms. The bill proposes to strike at the root of the matter by abolishing the existing department, and establishing in its place a department of Charities, and a department of Correction.

The desirability of such a change as this has long been apparent to persons who were aware how unwieldy the existing conglomerate department had become. In an earlier day, when New York was much

smaller than it has now become, it may have been desirable from some points of view to associate the city's dependants and delinquents under one management. But it long since became impossible to continue this alliance without serious detriment to the interests of the dependants at any rate, and perhaps of the delinquents as well. It hardly requires argument to show the unmanageableness of a department comprising hospitals, prisons, asylums, and almshouses to the number of twenty-five, with a population of 18,500. The only question really at issue is as to the feasibility of the proposed separation, and as to this there is equally little question in the minds of those persons best competent to judge, and whose judgment is unbiassed.

We trust that the Pavey bill will at once become a law. When the reforms it contemplates are put in operation, its benefits will be so manifest that the man with whose name it is associated, and those who have worked with him for the bill will be gratefully remembered for years to come by thousands of unfortunates whose condition it will ameliorate.

THE ETIOLOGY OF THE TIGHT WAIST.

The hand of science falls with a dull uncarnal thud upon the constricted waist of woman. It tells why she constricts, and that the purpose from the beginning was an unholy one. The women of Decadent Greece first began it in order to emphasize the proportions of their hips and exaggerate the delusive prominence of the bosom. The simple physiological act of respiration was perverted by the tightened girdle until the act became one of sub-clavicular enticement. In fine squeezing, the waist brought into lustful prominence the capacity of women for easy reproduction and subsequent plentiful lactation. Hippocrates denounced it in the women of Cos, Galen reproved the practice, Martial jeered at it, but still the waist was tightened and the double ovoid continued to glide before the ardent gaze of man.

The fact is, then, that women have tightened their girdles not because they wanted to do it, but because men approved of them and desired them the more for it. Why should women, then, be blamed? The practice is admitted unsound by all authorities, from Hippocrates to Dio Lewis, but men have insisted on it. Let the sanitarian and artist direct their attention, then, to man, the brute, not to woman, his victim. When this carnal but necessary factor in society and dress reform is cured of his evil ways, women will dress as they ought; but not before.

Congenital Spots or Anomalies.—At a recent meeting of the American Academy of Arts and Sciences, Dr. Stephenson, U.S.N., read a paper entitled: "Congenital Spots or Anomalies—A Means of Racial Identification; with Remarks on Linguistics in Connection with Migration of Peoples." Reference was also made to the studies of the Annamese savant, Petrus Truong Vinhky, of Cholon (near Saigon, Cochin China), and to his works on linguistics, comparative philology, etc. Such investigations, as well as examination of bodily peculiarities enable us to trace the origins and history of various peoples in their world-wanderings.

News of the Week.

The Medical Association of Georgia will hold its forty-sixth annual meeting in Savannah, on April 17, 18, and 19, 1895. The President of the Association is Dr. W. T. Westmoreland, and the Secretary, Dr. D. H. Howell, both of Atlanta.

Unusual Mortality in Connecticut.—The returns of the Connecticut State Board of Health, for February, show a death-rate nearly twenty-five per cent. higher than the average for the same month during the past five years. The greatest number of deaths from any one disease was from pneumonia.

Dr. W. G. Sampson died at his home, in Tiffin, O., on March 18th. He had practised in that State for over sixty years, and was ninety-two years old at the time of his death.

The Kentucky State Medical Society will hold its fortieth annual meeting in Harrodsburg, on June 12, 13, and 14, 1895.

The Charcot Monument Fund.—The sum of the contributions to the Charcot Monument Fund thus far received by the American Committee is $642.

A Woman's Hospital in Williamsburgh, N. Y.—A woman's hospital in memory of the late Robert Macoy is to be established in Williamsburgh by the Robert Macoy Memorial Association, which was organized about a month ago. As a commencement, Mrs. Elizabeth St. John has given the Association her house. This will be a training-school for nurses connected with the institution

The International Congress of Gynecology and Obstetrics will convene at Geneva, Switzerland, in September, 1896, instead of 1895 as previously stated.

Cases of Hydrophobia have recently developed in Florida and in Buffalo, N. Y.

Gift to a Hospital for Consumptives.—J. Pierpont Morgan has given $20,000 to erect a stone sanitarium at Liberty, Sullivan County, where consumptives will be treated. The structure will be on a tract of land consisting of two hundred acres, which has already been purchased.

Anti-Vivisectors and Plastic Surgery. — The story runs that Dr. W. W. Keen, of Philadelphia, wishing to transplant the nerve of a dog into the leg of a man, sent to the city pound for a dog. He there learned that the pound was controlled by the Society to Prevent Cruelty to Animals, the President of which, Mrs. Caroline Earle White, is opposed to vivisection. When Mrs. White learned what the Professor wanted she refused to permit him to have a dog, despite the fact that the life of a human being depended upon it. In her letter to the Professor, Mrs. White said: "In answer to your note I will say that, although I should always approve of sacrificing a dog's life in order to save that of a man, unless the latter was a curse to the world and the former a boon and blessing (which is sometimes the case), I think that I am justified in refusing to give

you one of the dogs at our pond for an experiment which may prove of benefit to one of your patients or may not, the latter being the most likely alternative." It thus seems that the lady knows a great deal about plastic surgery and the relative value of human and canine life.

A Yellow Fever Congress.—It is proposed to hold a congress on yellow fever during the Cotton States and International Exposition at Atlanta. The plan proposed is that the leading physicians of the city invite the leading physicians of the South Atlantic and Gulf cities, with a view of securing concert of action on quarantine measures and methods of dealing with the disease.

Death of Dr. Bernard E. Vaughn.—Dr. Bernard E. Vaughn, who was an assistant surgeon to the New York Cancer Hospital, and instructor in genito-urinary diseases at the New York Post-graduate School, died on March 5th. He was a native of Worcester, Mass., and was graduated from the College of Physicians and Surgeons, New York, in 1887. He was a member of the house staff of St. Luke's Hospital from 1887 to 1889.

Death of Dr. Dubois.—Dr. Robert Ogden Dubois died March 9th, in the thirty-sixth year of his age. He was a graduate of the Yale Medical School in 1881, but had practised in New York for a number of years.

Death of Dr. Azariah D. Newell.—Dr. Azariah D. Newell, one of the best-known physicians in New Jersey, died at his home in New Brunswick on March 9th, after a short illness.

Sir William Savory, Surgeon to St. Bartholomew's Hospital, died on March 4th, aged sixty-nine years.

The Storage of Antitoxin.—Professor Thomas R. Fraser writes to the *British Medical Journal:* "It seems to me that much unnecessary trouble is being taken in the storage and distribution of diphtheria antitoxin. I refer to the elaborate precautions which are required so long as it continues to retain its liquid form. I would suggest that in future the liquid antitoxin should, as soon as it has been obtained, be evaporated *in vacuo* over sulphuric acid, and stored and distributed in the form of a dry powder, whose exact quantitative relationship to the liquid antitoxin or to the toxin itself could easily be ascertained and stated. There can be no doubt that in this dry form diphtheria and all other antitoxins will retain almost indefinitely their original effects. Were this plan adopted it would also be possible considerably to reduce the bulk of fluid injected under the skin.

The New York State Board of Medical Examiners.—The State Board of Medical Examiners, representing the Medical Society of the State of New York, has made a report of its work for the year 1894, which contains a number of interesting data. The total number of candidates actually examined was 536. Of these, 470 were examined by the Board representing the Medical Society of the State of New York; 59 by the Board representing the Homœopathic State Medical Society; and 7 by the Board representing the Eclectic Medical Society of the State of New York. Of the first, 316 passed, and 32.7 per cent. were rejected. Of the second, 46 passed, and 22 per cent. were rejected. Of the third, 3 passed, and 57.1 per cent. were rejected. Seventeen candidates were rejected a second time; 6, three or more times; and 54 were unable to secure a license.

It appeared that, whereas prior to 1891 the number of physicians locating in the State of New York was from 700 to 800, there are at present less than 400. The fact, however, that there were 536 applicants is accounted for not only by an increase in the number of medical men, but principally by the fact that the State license has become a matter of such importance that most of the States having boards of medical examiners accept them as licenses to practise, without exacting added medical tests. Under the provisions of the law the Board of Medical Examiners is permitted to indorse as sufficient to practise the licenses issued by other State boards of medical examiners, provided the standards of these boards are not lower than those of the New York Board. Numerous applications from various States were received for this indorsement, but on investigation it was found in each instance that the standard was not sufficiently high to warrant approval of the documents submitted. The Board complains that the preliminary education of medical students and candidates for the licensing degree in the State of New York is not satisfactory. It finds that while the standard is far above that established in other States, it is still insufficient and not on a par with the requirements exacted from students of other professions in the State. In accordance with this opinion the Board adopted a resolution, declaring that the best interests of the public and of the medical profession would be materially advanced by gradually increasing the minimum requirements as to general preliminary education, until no candidate be entitled to matriculate in 1897 at a degree-granting medical school who shall not have completed at least a full high-school course. The public may well congratulate itself upon the outcome of the agitation directed to its welfare and interest, instituted and carried to a successful issue by the medical profession.

Foot and Mouth Disease Attacking Human Beings.—A cablegram announces that physicians throughout Europe are somewhat apprehensive of the spread of what is described as the human form of the foot and mouth disease, which has been, for a considerable time, prevalent in Berlin. Specialists who have investigated declare that the bacteria are identical with those of cattle suffering from the complaint. They report the pestilence as dangerous, and say it is causing frequent deaths among human victims. Professor Virchow and a committee of the Berlin Medical Society are making an investigation of the milk, which is said to be the usual vehicle of the contagion.

Dr. Edward H. Peaslee has been appointed School Commissioner.

A Surgeon Gets His Fee.—Dr. Emil Schopen, of Yonkers, brought suit to recover the balance of a fee for surgical attendance on Mrs. H. R. Baldwin. Mrs. Baldwin was injured in an accident on the Hudson

River Railroad in 1891, when several persons were killed. Among the operations performed on her were the removal of the left hand, three fingers from the right hand, the removal of both eyes and ears, and the building up of a new-growth of skin on the skull. Dr. Schopen treated Mrs. Baldwin for sixteen months. His bill was $3,000. He sued for a balance of $1,400. The jury gave the doctor $1,150, which seems little enough for all that was done.

The Coroner to be a Lawyer.—The following report of the special committee of the Medico-Legal Society has been submitted to the Legislature:

"To the Honorable the Legislature of the State of New York:

"The select committee of the Medico-Legal Society of New York, to whom has been referred Senate Bill No. 81, introduced January 14, 1895, by Mr. Senator Guy, entitled: 'An Act to Amend title Four Hundred and Ten of the Laws of 1882,' entitled, 'An Act to consolidate into one act and to declare the Special and Local Laws affecting public interests in the City of New York,' so far as the same relates to coroners. Respectfully report: 1. That they approve of the Bill so introduced by Senator Guy and recommend its passage. 2. That they recommend that the coroner so to be hereafter chosen should be a counsellor-at-law of at least ten years practice. 3. We recommend that the Medical Examiners shall be skilled in Medico-Legal Science, and selected with regard to their professional fitness, and without reference to political considerations. 4. We recommend that line 20, section 1779 of proposed Bill be amended by changing the words 'Police Justice' to the words 'Justice of the Supreme Court,' as the office of Coroner in our judgment under the law should rank with that of a Justice of the Supreme Court.

"Respectfully submitted, March 9, 1895. Clark Bell, *Chairman;* A. H. Dailey; H. W. Mitchell, M.D.; Moritz Ellenger; Wyatt Johnson, M.D.; T. H. Tyndale. Unanimously approved by the Medico-Legal Society, March 13, 1895."

Voluntary Admission of Patients to Hospitals for the Insane.—The following resolution, relating to the voluntary admission of patients to Hospitals for Insane, was adopted at the session of the Medico-Legal Society, held on March 13, 1895:

"*Resolved*, That in the opinion of this Society the adoption of a law permitting voluntary admission to hospitals for the insane, of such persons as may desire treatment therein is eminently proper and desirable, and the highest interests of the insane demand the incorporation of such a law among the statutes of the State of New York."

Schweningerism.—Schweninger, by the grace of Bismarck, Professor, gives these details of his anti-fat treatment: "Eat as much as you please as often as you like; but not too much at a meal. Drink no liquid at any meal. When thirsty drink a little good aërated water, with a few drops of lemon or orange juice squeezed into it; but only an hour before or an hour after meals. You may also take a little white wine or cider that is not sweet, or now and then a cup of tea, but never coffee. Smoke a little, and indulge with moderation in the other little luxuries to which you have been accustomed. Bathe often, but do not wet the entire surface of the body at once. Exercise should be regular. Change your position as often as possible. Do not remain standing or sitting or lying too long at a time, nor pass too many hours in bed. Take your meals at a different hour every day. Never eat at regular hours, but whenever you are hungry; and, if it be not too soon before or after a meal, drink whenever you are thirsty. Better eat a dozen times a day than overload your stomach at two or three heavy meals at long intervals. Do not eat the same article of food too often."

Dr. William T. G. Morton.—Among the fifty-three names which are to be inscribed as a roll of honor in the dome of the new chamber of the House of Representatives, in the State House, at Boston, and each of which is intended either to mark an epoch or to designate a man who has influenced the course of events, we note that three were borne by members of our profession. Only one of these three, however, was chosen on account of eminent services to medicine. The name so dignified is that of Dr. William T. G. Morton, who was the prime mover of the experiments which led to the establishment of anæsthesia by sulphuric ether as a matter of practice. Of the priceless value of this boon to the human race it would be superfluous at this day to speak. That the name of the man through whom it came should be held in lasting honor, and given a high place in the list of benefactors to mankind is but just and right.

A Lavish Digestive Cavity.—Commenting on the statement of the Medical Record that, at a late meeting of the New York Academy of Medicine, "Dr. Achilles Rose exhibited a cannon-ball, weighing over three pounds, a form which had given satisfaction to himself and others in constipation," the *Railway Surgeon* remarks: "Any man who would take three-pound cannon-balls must have a lavish digestive cavity, and an awful constipation. The generous pink-tinted oral cavity of the hippopotamus might smoothly gulp them; but we would not, for our part, take them under any circumstance unless they were powdered or sugar-coated. They will never be popular. This is too much like heroic medicine."

Female Professors in Medical Colleges.—The College of Physicians and Surgeons of Kansas City now has a lady professor in the person of Dr. Katherine Berry Richardson, who occupies the chair of Visceral and Histological Anatomy. The Board of Regents of the University of Michigan has removed the barrier of sex to the occupancy of its chairs, and a movement has been set on foot in Detroit to endow a female professorship. It is estimated that a capital of $30,000 will suffice for the endowment of the chair, and one enthusiastic advocate of the rights of her sex has already subscribed $10,000, while four others have among them given $4,000.

The Estate of the Late Dr. Oliver Wendell Holmes amounted to $112,000.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 7, 1895.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

The Index Medicus. — On motion of DR. GEORGE THOMAS JACKSON and at the recommendation of the Council, the President was directed to appoint a Conference Committee, preferably the present Library Committee, to confer with committees appointed by other libraries with regard to supporting the *Index Medicus*, the publication of which Mr. Davis had continued at personal loss, and which must be discontinued unless two hundred additional subscriptions or $2,000 were secured. The President appointed the present Library Committee. At the request of the Committee on the Bureau for Nurses, the Bureau was placed in charge of the Executive Committee for the present.

Malnutrition, Practically and Physiologically Considered.—DR. J. HARVIE DEW, opened a general discussion on this subject with a paper. Malnutrition, he said, could not be classified as a distinct disease, and yet because of its relative importance it should have a well-recognized place in the literature of medicine. Correctly defined, it was an incidental symptom or condition, but always one to be considered with the greatest care in the scientific management and treatment of disease. The energy-producing and spending capacity of all animal bodies depended directly upon the activity with which the processes of nutrition were conducted and maintained. The continued accomplishment of this essential requisite made it necessary that a large number of organs and functions should be in good, if not perfect, physiological order. There must be a comfortable condition of mind and body, and a relish for food; mastication must be complete, and the stomach capable of receiving and holding food; the digestive fluids must be sufficient in quantity and up to the standard in quality; the absorptive capacity of the blood-vessels and lymphatics along the alimentary canal must be active; the peristaltic and eliminative work of the bowels must be normal; the heart's action must be sufficient in force and regular; the blood must be suitable in quantity and in oxygen-carrying capacity; the processes of tissue assimilation must be physiologically correct; the elimination of waste matter through the excretory organs must be effectually accomplished.

If we consider for a moment this large and formidable array of functions and processes necessary to perfect or normal nutrition, it would be easy to understand that diseases, indiscretions, imprudent indulgence, and exposure of any kind might readily disturb one or more of them and thus lead in the end to malnutrition. The intimate relationship of the nerves of the various organs of the body serving as a basis of uniting and harmonizing one with the others would account for the fact that organic disease of any kind would sooner or later disturb a number of these nutritive functions. Especially was this the case where the febrile reaction reached a high degree. When the illness or disturbed functional conditions had continued any length of time the active symptoms of malnutrition exhibited themselves in loss of or defective digestion, abnormal bowel action, weakness or languor, depressed heart action, nervous disturbance, loss of weight, etc.

In the treatment of progressive disease the physician endeavored by every possible means to maintain the nutrition of the patient, giving the most nourishing and most easily digested food, stimulation, etc. When the disease was at an end the work of building up or restoring the energies began by correcting the functional disturbances through which malnutrition had been induced. In the great majority of cases this afforded the promptest possible means, and he wished here to impress the fact that in general medicine there were few well-established specifics. Whatever might be the capacity of the knife and certain remedies resorted to by specialists and general practitioners for the removal of certain pathological conditions, it must be remembered that the removal of any evidence of malnutrition, and the improvement of the general health of the patient, played a most important part, and often the essential part, in effecting a complete restoration.

When the physician had overcome the condition of malnutrition, the patient might be heard to say for months or even years afterward that he had never been so well as since that spell of sickness, which he regarded as a blessing. On the other hand, when proper attention was not given to restoring the damage, nature struggled up to a certain point, stopped its efforts at repair, and the patient would be heard to say that he had never been well since that last sickness. This showed the necessity of restoring the nutritive functions, if possible, to their normal condition before pronouncing the patient cured.

In the treatment of malnutrition many physicians declared medicines of no value, and trusted to good food, change of climate, etc. In some instances these might prove sufficient in themselves to accomplish complete restoration, but in the great majority of cases the patient's means or business would not permit of him carrying out such instructions, and in any event the judicious use of medicines would aid. The original cause should be removed where possible. Then, no fever being present, the next point to consider was the condition of the alimentary canal and the secretions necessary to its functions. The bowel should be kept free. Often calomel was of service, with or without some purgative, as rhubarb or cascara. Loss of appetite would often be found due to lack of flow of digestive fluids. When fever was not present, and the active processes of the disease were at an end, the bitter tonics were indicated before meals. Catarrhal processes arising from imperfect digestion during the illness called for hot water, hydrastis, etc. In many instances where food led to gastric discomfort an excellent result followed the use of infusion of hops. In anæmia following the febrile state there was deficiency or impairment of the blood-corpuscles and of their capacity to carry oxygen. In some instances fresh air, etc., would restore the deficiency, but often iron was of great aid, and a bitter tonic would add to its efficacy. One or more of the digestive fluids were liable to be deficient in some of their ingredients, which might be learned by a study of the case, by trial of diet, or by use of the digestive ferments. Alcoholics in some form, judiciously administered with the food, were of value in many cases, having a stimulating effect like kindling-wood in a fire. Black coffee after dinner had a stimulating action on account of its bitter properties and the caffein which it contained. The addition of some hydrocarbon, like cod-liver oil, was often of great value.

Another type of malnutrition was of interest because it was not the outcome of any special or definite disease, but was more likely to be the result of habit, and might date back to childhood. He referred to persons met with in every walk of life, who always had an emaciated, badly nourished appearance. They might live to old age without serious discomfort. The majority of them did not take sufficient food or fluid to supply the physiological needs of the body, while others took an immense quantity, but it passed through undigested and unabsorbed. The physician was able to greatly improve the bodily and mental state of the former class by prescribing a more liberal diet, adding perhaps a pint of milk (in a form most suitable to the case) between meals, and bearing in mind the fact that the body by weight was two-thirds fluid. In the second class at-

tention should be given the kind of food instead of increasing the quantity.

Dr. Dew said, in conclusion, that his object had been to give only an outline of this very broad subject, malnutrition, as it was impossible to consider all its features in one paper.

The Treatment Must Vary with the Case.—Dr. A. Jacobi thought he had never risen to participate in a discussion with greater misgivings than to-night. The author had gone rapidly over the whole field of physiology and pathology, and a good deal of that of materia medica, and it seemed there was very little more to be said on the general subject of malnutrition. He was quite in accord with the paper.

Regarding nutrition and nutriments, he said it was a peculiar fact that when we had to deal with even the best so-called nutriments in the world we found that what was good for one individual might be far from being good for another. For instance, it was admitted that milk was the best nutriment for the young and for the old, but particularly for the young. On the other hand, we knew that if we gave milk to a child suffering from malnutrition and paid no heed to its effects, we were liable to make a grave mistake. A baby might not thrive on its mother's breast; it might on another's breast; and there were some which thrived only after being placed on artificial food. Why? Because there was not uniformity of the digestive organs and of the digestive secretions in different individuals. This was only one example of a great many which might be cited, showing that positive rules could not be made in dietetic treatment of malnutrition. Nothing was more erroneous than to suppose that in every case of anæmia, or every case of malnutrition, iron was the proper thing. For instance, in anæmia due to gastric insufficiency iron was not indicated at all. As long as the stomach was not in proper condition iron ought not to be given. Yet he knew of doctors prescribing it in inflammatory conditions before the fever had subsided. In many cases arsenic was better than iron, but, again, there were some persons who could not take arsenic at all. The author had well stated that malnutrition was only a symptom, or a complex of symptoms, resulting from some change in the physiological condition of one or more organs. In malnutrition depending upon brain neurosis, if there were acute symptoms, avoid alcohol and coffee. One should also avoid alcohol in nephritis, although it might be useful in some other cases of malnutrition. He repeated that malnutrition was not a disease in itself, but a symptom, and the treatment must vary just as in anæmia, which also was dependent upon a variety of causes, or was of different forms and called for treatment according to the case and not according to the name.

Causes of Malnutrition Classified.—Dr. W. H. Thomson said that when the author had asked him to discuss the subject of malnutrition he had replied that it was a subject as wide as all outdoors, and therefore he would not attempt to touch upon more than one phase of it. Every therapeutist should start out with the principle that he was treating the patient instead of his disease, and should remember that there was one significant symptom which should have his attention in order to correctly shape his efforts, namely, that form of malnutrition which led to emaciation. While the causes of emaciation might seem extremely numerous, yet on reviewing them it would be found that they could be generalized under six or seven heads, and that others were very exceptional. Each one of the causes which he was about to name went very far toward shaping our therapeutic procedures. The first and commonest cause of emaciation was fever. The very term febrile emaciation suggested at once that emaciation meant something very different from being merely thin. A person might be very thin and yet have no signs of being emaciated. True emaciation was a loss of every tissue but one. The exception was the nervous system, which Dr. Thomson said never lost in bulk. Unless there were a loss in muscular tissue, and also in bone, the case could not be classed as one of real emaciation, notwithstanding a diminution in weight; it was simply one of reduction of fat. This was almost always true of jaundice, where the thinness was due to loss of fat, while the muscles and bones remained the same. In contrast therewith was the thinness of phthisis.

Fever giving rise to emaciation was almost synonymous with a toxic cause. Having mentioned pulmonary tuberculosis as one cause of fever emaciation, Dr. Thomson placed in the same category the emaciation of pernicious anæmia. While this was called an anæmia, yet it was a type of fever. Not all forms of anæmia led to emaciation; for instance, chlorosis. The emaciation connected with febrile conditions was likely to last as long as the fever continued, and this in turn would remain until we got rid of the toxic influence. The treatment of the malnutrition, therefore, must be symptomatic unless we could counteract both the toxic origin and the febrile process.

The second great class related to disorders of the alimentary canal. In gastric dyspepsia, ulcer, and other organic conditions attended with vomiting, emaciation would come on sooner or later, and he had been led to seek first and last for something which the stomach would digest. There was a marked difference between diarrhœa and dysentery; diarrhœa seldom produced emaciation, although it lasted for years, while dysentery caused emaciation from the fact that the reflex irritation and excessive peristalsis hurried the food from the stomach on to the rectum; it could not remain long enough to be digested. Here he remarked that nervous disorders did not cause emaciation, with certain exceptions, as some forms of insanity.

A third cause was malignant disease; a fourth, diabetes mellitus. Further causes were very uncertain. For instance, one might suppose Bright's disease was a cause, but almost invariably the emaciation seen in this disease was due to one of the other causes mentioned, more exactly gastritis. The speaker thought that in Graves's disease the cause was in an intestinal poison, and by attention to diet, giving milk and cutting off animal food, he had usually been able to arrest the emaciation. In chronic articular rheumatism, he doubted whether fever was not the sole explanation of the emaciation.

Treatment by Abundance of Food and Rest.—Dr. Landon Carter Gray remarked that any man who had been in practice ten or twenty years must appreciate the fact that text-books did not deal with many questions which came up in every-day life. In the early years of his experience he had seen many cases of nervous diseases, mostly of subacute or chronic type, in which it was exceedingly difficult to get results which were pleasing, either to himself or to his patients. After some years of varying failures he came across Weir Mitchell's book on "Fat- and Blood-making," took a trip to Philadelphia, spent several days with Mitchell, and came away perfectly persuaded that he was making such marvellous cures as he was credited with by the popular voice. Returning home, he applied the method to some of his own patients, and was frightened to see those who had been reduced to living skeletons, by seeming inability to take food or by vomiting, begin, after a week's confinement to bed, massage, and compulsory feeding, to take and even relish three meals a day, and a quart of milk and a pound of beef converted into beef-tea between meals, and when he had seen the urine crowded with amorphous urates, he had been still more frightened. Nevertheless the patients had gotten well, and had remained well, dating their return of robust health back to that sickness.

Dr. Gray could not agree with Dr. Thomson that nervous diseases with few exceptions did not cause emaciation. He had seen it in myelitis, in neuritis, in

syphilis of the brain and cord, in different forms of paralysis, and, of course, in neurasthenia, although there was grave doubt in his mind as to how far anæmia was not due to the condition of the intestinal tract in neurasthenic patients.

In treatment it was less a question of the kind of food in most cases than of quality, quantity, variety, and good cooking. He had found again and again that good results came in almost hopeless cases by impressing upon the patients the necessity for taking a large quantity of food, even though they had not much appetite for it.

Just as great difficulty was encountered in leading persons who had got into a condition of malnutrition to understand that they could not continue to work up to their full physiological limit, mentally or physically. They must rest until by taking and appropriating an extra amount of nutriment their former physiological state had been restored. There would be nothing unreasonable in compelling an elephant to pull a furniture van to Central Park, but to require a child to do the same thing would end in double murder.

The necessity for good cooking might be impressed by relating a story which he had once heard of a man who had had his house newly furnished, and while congratulating himself upon the result was reproached by his wife for not having a sufficient number of mottoes upon the wall, such as "God bless our home." He responded that he would be willing to comply with her wish if she would have one put up in the dining-room, "God damn our cook." However, Dr. Gray thought the cooking in this country had been improving, and this might account in some degree for apparently a diminution in the number of dyspeptics.

Malnutrition from the Standpoint of the Dermatologist.—Dr. P. A. Morrow supposed that the advocates of the local origin of skin diseases would not be inclined to assign much importance to malnutrition as an etiological factor. But in common with most dermatologists in this country, he believed there was a close relation between disorders of the alimentary organs and the skin, and that there were a large number of skin affections which were purely symptomatic of disorders of nutrition. Nutritive disturbances played an important part not only in initiating diseases of the skin, but also in perpetuating them. It was very evident that the skin would participate in any impairment of nutrition, and by virtue of this its capacity for resistance was diminished. The influence of malnutrition in the production of skin diseases was perhaps most conspicuous in the extremes of life, in infancy and in old age—in infancy, when the elements of the skin were in the process of development and consolidation, and at a more advanced period, when there was a tendency to degeneration of the cutaneous structures. In the former, a familiar example was skin diseases of eczematous character. Half the cases of skin affections in children belonged to this class, and a common cause was insufficient or improper food, whether breast-milk or other kind. In old age we saw senile pruritus, epithelioma, etc., resulting from malnutrition and a tendency to degeneration.

Whether we accepted the traditional French doctrine of a dartrous diathesis or not, Dr. Morrow thought we must recognize the condition in which there was an excess of uric acid and oxalate of lime as so constantly associated with certain forms of skin disease as to almost certainly stand in the relation of cause and effect. In many cases of syphilis a satisfactory result could not be obtained from specific remedies until we had overcome a condition of malnutrition.

The Influence of Malnutrition upon the Throat, Nose, and Ear.—Dr. R. C. Myles considered the subject in two relations: 1st, to what extent did malnutrition affect the nose, throat, and ear? 2d, to what extent did abnormal conditions of the nose, throat, and ear produce malnutrition? In his experience malnutrition did not affect the nose, throat, and ear nearly as much, nor as often, as was usually inferred. Excluding special diatheses and diseases, such as tuberculosis and syphilis, malnutrition manifested itself chiefly upon the nerves and muscles of the larynx, upon the auditory nerves, especially tinnitus and passive congestion phenomena, upon the nose by diminishing its heat-producing properties, by thickening the mucus and causing œdema of the membrane. On the other hand, excessive local conditions, hypertrophic and proliferative, had frequently been causes of general malnutrition. For instance, malnutrition produced by great loss of saliva, great quantity of muco-purulent matter entering the stomach, or flowing into the bronchi and causing bronchitis, which in turn led to general malnutrition. The history of medicine was replete with cases where local trouble in different parts of the body having been removed, the nutrition and general health were restored.

Electricity in Malnutrition.—Dr. A. H. Goelet thought every case of malnutrition must be treated upon its merits, and a clew to the treatment would often be furnished by examination of the blood and of the excretions. But what he wished especially to speak about was the value of electricity in improving the nutrition, more especially the faradic and static currents. He mentioned some, and could mention many more instances where the improvement in general nutrition was out of all proportion to the influence on the local condition to which the current had been directed. On the other hand, a case was cited in which the local and general improvement had both been remarkable. A girl of seventeen years, reduced to sixty pounds in weight from a uterine fibroid extending up to the umbilicus, and too near death to admit of hysterectomy, which some gynecologist had suggested, was treated systematically with electricity, and improved so rapidly that she was soon able to go out, had now attained to a weight of one hundred and twenty-five pounds, and the tumor had been reduced to the size of a walnut. In addition to diet and medicines to correct malnutrition, something was required to stimulate the secretions of the body, and electricity had that effect.

Dr. M. L. Rheim spoke of the effect of malnutrition in diminishing the vitality of the gums and tissues on which the teeth depended for their sound state, and said that, on the other hand, he had frequently seen small amounts of pus exude from around the teeth, and, being swallowed, interfere with the digestive processes and lead to malnutrition.

Wooden Bread.—A German periodical devoted to wood industries announces that food products consisting partly of wood are now manufactured. At Berlin a factory has been built which is turning out about two hundred quintals of wooden bread a day. Sawdust is subjected to chemical treatment, after which it is mixed with one-third farina and prepared like ordinary bread. The product at present serves only as food for horses, but the Berlin Tramway Company, which is the most important customer of the factory, is well pleased with the results. The manufacturers say that wooden bread constitutes also an excellent food for man.—*The Sun.*

A Convincing Temperance Argument.—An English temperance agitator, Miss Weston, publishes in *Ashore and Afloat*, under the caption of "A Drunkard's Brain—No Joke but Awful Truth," a statement that at an inquest recently held upon a noted drunkard, on opening his skull, "the odor of alcohol that filled the room was sickening. One of the surgeons then struck a match and held it close to the head. Immediately a blue flame enveloped the whole of the exposed brain." Miss Weston seems to regard truth as a matter of slight importance compared to the virtue of total abstinence.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Special Meeting, March 16, 1895.

EGBERT H. GRANDIN, M.D., PRESIDENT, IN THE CHAIR.

The Rights and Privileges of Physicians Called to Cases of Abortion, etc.—The SECRETARY read the call for the special meeting, signed by twenty members, as follows :

Whereas, a number of instances have occurred in this city where reputable members of this Society have been arrested for complicity in malpractice cases, without even the shadow of a reason for such action on the part of the police ; therefore, we, the undersigned, respectfully request you to call a special meeting of the Society for the purpose of ascertaining the rights and privileges of physicians who may be called to attend cases of abortion, etc.

THE PRESIDENT stated that, in the judgment of the members who had signed the call, an indignity had been offered the profession, an indignity which, if not protested against, might become a precedent for the infliction of a similar indignity on each and every physician when, in the pursuit of his vocation, he was called to the bedside of a dying woman. It would seem that the profession was impaled on the prongs of a dilemma which confronted it whichever way it turned. If we did not respond to calls of this nature we were termed, and rightly so, unfeeling and unworthy the name physician ; if we did respond, and on suspicion reported the case to the authorities, if the suspicion proved unfounded, it was a question whether we were not open to a suit for libel ; furthermore, if we did report the case and the symptoms supported the suspicion of malpractice, we were liable to arrest and the consequent notoriety. We were here, then, to counsel together calmly, dispassionately, as to our rights and privileges in this matter. The medical profession of this city had always stood on the side of law and order. We were here to protest in a forcible manner against the assumption that the presence of a medical man at the bedside of a dying woman was *ipso facto* evidence of wrong doing, of being an accomplice in a criminal act performed before our advent. We were here possibly also to express again, as we had over and over again, our utter abhorrence as medical men of criminal fœticide. And while we were about it, we might as well inquire why this crime not only existed, but seemed to be on the increase in this community. The President felt that the statement would pass unchallenged, that a reputable man had never in this city been found guilty of criminal abortion. It was the midwives, and the men under the guise of specialists in diseases of women, the notorious abortionists, who committed this crime, and who were found out, who were indicted, and who were rarely punished. It was proper, therefore, to ask if the blame for the existence of this evil in this city might not properly be laid at the door of the officers of the law. It went without saying, that if swift justice were meted out to these miscreants, the abortionists, they would find this city so hot for them that after a time criminal fœticide would cease to exist in this community, so far as it ever would cease to exist.

The President said Dr. Marx would relate a recent case in this city which would give the members food for thought and discussion.

A Recent Case.—DR. S. MARX then related the case reported recently in the daily papers. A reputable member of the Society had been called to see a young woman, recently a widow, at the house of a midwife. Both parties denied absolutely any form of operation. The patient had ceased to menstruate about four months before, was bleeding, and could give no cause except lifting heavy tubs. Having no other place to go under such circumstances, she had entered the house of the midwife. The doctor made an examination, found the uterus about the usual size at four months pregnancy, filled with detritus, there were symptoms of sepsis. The treatment was such as the conditions justified, but as the patient got worse another reputable physician was called, to whom the patient and midwife told the same story, denying criminal procedures. As the physicians were not in a position to remain all night with a dying woman, they advised that a hospital ambulance be called. Notwithstanding that they had complied with the law to the letter, they were taken from their offices by the police to a police court. Before dying, the woman exonerated the doctors and incriminated the midwife. The coroner listened to the story of the detectives and not that of the physicians, and demanded bail of the latter, which finally was made only nominal. The coroner's inquest showed that the abortion had been committed by the midwife, and that the action of the two physicians connected with the case was simply in line with the duties of their profession, and that they were in no way implicated in the criminal operation.

THE PRESIDENT remarked that here was an example, then, where two physicians had been arrested in the performance of their duty, and without the shadow of a reason. It was true they had been acquitted before the coroner, as might have been predicted, but the story of their arrest had been read in the papers by thousands who thereafter associated them in their minds with abortionists, while the coroner's report probably had not been read by five hundred.

Another Case.—DR. A. Y. REID related his own experience with a case of alleged criminal abortion in 1892, a full history of which may be found in the New York *Medical Journal*, April 8, 1893. The points which he emphasized were that any physician was liable to be arrested in the discharge of his duty in connection with cases of abortion, or possible abortion ; that there were some men who, under their guise as officers of the law, sought in cases of this kind to incriminate reputable physicians for purposes of blackmail. The coroner in his case laughed at the idea that he would be able to get a jury of reputable physicians, and said he could himself pick out one who would bring in such a verdict as he thought fit. In Dr. Reid's former report of the case we find that the following eminent members of the profession actually served on the coroner's jury : Drs. Mundé, Dudley, Boldt, Grandin, Sims, Jacobus, Janvrin, Van Santvoord, Coe, Goffe, Peaslee, and Morrill. Besides absolutely exonerating Dr. Reid, the jury said in its verdict : " This jury desire to express their condemnation of an apparent too great readiness on the part of some persons connected with this case to incriminate, without sufficient evidence, a reputable physician, and thus subject him to the indignity of arrest and criminal prosecution."

A friend afterward heard a police captain say that Dr. Reid would thereafter have to enter the ranks of the abortionists ; meaning that legitimate practice would leave him. Such was known to be the usual effect of allowing one's name to enter the newspapers in connection with cases of abortion, however innocent he might be. The result had not been as predicted in this instance ; his patients had remained with him, yet there was no doubt but what his practice had suffered considerably, while the legitimate expenses connected with the case had been over $700. He had no doubt but that there were many physicians in the city who were paying blackmail to the police to be permitted to practise their profession legitimately, because some time in the past, when inexperienced, they had begun to do so to prevent their names from entering the public press in connection with some case of abortion with which they had had no criminal, but simply professional, relations.

DR. JOHN IRWIN thought it might be well to exclude

the reporters of the press on this occasion, so that members might feel freer in relating their experience. The motion was lost, no affirmative votes.

Physicians not Good Citizens.—Dr. A. Jacobi said he arose to speak, not simply as a physician, but as a citizen of the city of New York. We all knew what these things meant. These proceedings on the part of the police officers had been of the same character as that noticed in the papers two days ago, where a reputable citizen was held up by an officer in uniform and taken to a police station. The same thing might have occurred to a doctor on his way to see a patient, and he might have handed over five or ten dollars in order not to be detained or to avoid sleeping in a station. Indeed, he did not doubt but what some present had done that very act, and were now ashamed of it. We had been exposed to robbery of all kinds, and to violence as no city in Europe would permit. And we were all at fault, for we were not good citizens. We had not participated in public affairs. If we would rid ourselves of the danger of being held up in the street, and of being taken from our offices to the station-house, we must attend public meetings; must be at the primaries; must go to the polls, not in a body as physicians, but one and all as citizens. As a profession he did not think we could do anything. The common run of politicians cared not what we did so long as we had no votes. Our protest amounted to nothing except at the primaries and the ballot.

Dr. C. A. von Ramdohr mentioned three cases in which he pronounced the action of coroners or deputy coroners as officious, if indeed it was not based on inefficiency or corruption. He differed from Dr. Jacobi, and believed that the Medical Society of the County of New York could do something. He had once asked a judge of the Supreme Court what he should do in cases of the kind under discussion, and received two replies, one private, the other professional. The first was never to report a case of abortion which might come to his knowledge; the second, never to meddle with a coroner's office, nor with the office of a police justice, but to go to the office of the district attorney; it was more decent.

To Obtain Legal Opinion.—Dr. von Ramdohr then moved that the Society obtain legal opinion as to whether doctors had to report cases of abortion which came to their knowledge in the course of their professional duties, to whom must they make the report, and when.

Later this motion was adopted, after having been amended to refer the question to the Comitia Minora and the counsel of the Society.

Dr. John A. Irwin contended that it was not for the physician to report to the authorities any case of abortion. For his own part he declined to play the detective at any time whatsoever. His first and only duty was as a professional man. If called to a patient in distress he did whatever he could do to relieve her, totally ignoring the crime which might have been committed in the first instance which brought on the distress.

Dr. A. Jacobi read a few lines from Field's Medico-Legal Guide, which expressed his own opinion, and was in line with the remarks of Dr. Irwin: A person duly authorized to practise physic or surgery shall not be allowed to disclose any information which he acquired in attending the patient in professional capacity which was necessary to enable him to act in that capacity. But the patient may waive the privilege thus secured him by the State, and permit his medical adviser or attendant to disclose such information.

In Dr. Jacobi's opinion, as long as the doctor went to a case of criminal abortion his lips were sealed, and he had nothing whatsoever to do with the police unless the patient waived the privilege of secrecy.

Dr. Bruce made some remarks, and suggested that the counsel of the Society ought to defend members in cases of this character, which would be equivalent to a defence by the Society. The President replied that the services of the Society through the board of censors were at the disposal of every member who might happen to be under the charge of criminal abortion of which he was not guilty.

The Coroner's Side.—Dr. E. W. Hoeber spoke from the point of view of the coroner, he having been one elected last fall. He agreed with Dr. Jacobi that it was the fault of physicians that they were in the position of which they complained. They voted for men to fill the office of coroner who were not physicians, and who therefore could not be expected to understand so fully the needs, the rights, and the privileges of the medical profession. One speaker had mentioned deputy coroner, there were no deputy coroners, but there were coroners' physicians, and it was true they were liable to make mistakes, but so were other physicians. The doctor who said he would not report a case simply ignored and disobeyed the law. Ignorance of the law was no excuse, he would be held as an accessory if he knew of a crime and failed to report it. The patient whose case Dr. Marx had related was in the house of a midwife who had advertised in the papers for years. The doctors who were called ought to have known this, they ought to have suspected that this woman had committed a crime, and learning the fact, ought to have reported it to the authorities. If the law requiring us to report such cases was unjust, we should seek to repeal it. Practically, it was only women who died, and who died under suspicious circumstances, whose cases came before the coroner or police authorities, and because of lack of evidence it was of little avail for the physician to report a case until he saw that his patient was likely to die.

The discussion was further participated in by Drs. Tuttle, Vedin, H. S. Stark, Michaelis, and others, and a motion offered by Dr. Stark was adopted, calling for an expression of an opinion from the counsel of the Society with regard to the medico-legal position of physicians when called to cases of criminal abortion, this opinion to be printed and distributed among the members.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

INFLUENZA—FRESH EPIDEMIC IN LONDON—MORTALITY—INVASION OF THE PROVINCES—DIPHTHERIA—SMALL-POX—THE VACCINATION COMMISSION—CHELSEA HOSPITAL FOR WOMEN AGAIN—THE CORK CLUBS.

London, March 2, 1895.

We are in for influenza again. Last week though a number of cases were reported there remained some hope that we should only have a slight recrudescence of the disease. This week its rapid spread and in numerous cases its grave type make it almost certain that we are already in a severe epidemic. Pneumonia and other serious complications are found in a considerable proportion of the cases and accordingly the death-rate will probably prove high. The fact that Lord Rosebery has been prostrated by the disease has naturally drawn public attention to it, besides which a great number of public men are in the like case. It is common enough, however, to hear the attacks derided as "fashionable" or "convenient," by those who have not suffered from it. After an attack, however, it is noticeable that the patient speaks with more respect of "the flue" as it is often called, and is much more careful to avoid exposure. The Registrar-General reports one hundred and eleven deaths directly due to influenza last week (*i.e.*, in the week ending 23d ult.), and there were also many cases in which patients suffering from

other diseases were attacked and died. In the previous three weeks the deaths had been registered of sixteen, thirteen, and twenty-four patients.

The epidemic seems especially severe in the West End, but the spread of the disease is so rapid that other districts will probably not have many days of comparative immunity. The epidemic has also appeared in several provincial towns and seems likely to rapidly spread all over the country. In Edinburgh it is at its height, and in Dublin it seems to be making way. No doubt many of the deaths from respiratory diseases last week were due to the epidemic influence. The deaths from this class were more than double the average. Pneumonia and bronchitis bulk largely in the returns, and there is excessive mortality among the aged. In view of the epidemic there seems a disposition to forget the effects of the severe cold we have experienced. I cannot but think that no small share of the mortality from respiratory diseases is really due to the extreme weather, which has in other ways proved so fatal.

Diphtheria has been below the average, and in the last weeks the deaths have been twenty-nine, forty-five, thirty-four, twenty-nine, the corrected average being thirty-one. Small-pox shows a disposition to increase, particularly in Marylebone, in which parish the late outbreak occurred, but the sanitary authorities are taking vigorous measures to meet the danger.

This reminds me that the commission on vaccination still delays its report. This is now I believe the sixth year in which it has "dragged its slow length along." No wonder that explanations have been asked for in both Houses of Parliament. The reply was that the commission had practically concluded its labors and the report was in preparation. But the Lord Chancellor let out that some of the delay was caused by outbreaks of small-pox in various parts and the commission had thought it advisable to have inquiry made into them by skilled persons. Rather an extraordinary manner of fulfilling their commission to thus burden themselves with investigations for which they were not appointed. But a "poor excuse is better than none," and this is no doubt a very poor excuse for unreasonable delay. It would be if no consequence, but that the existence of the commission has increased the difficulties of local authorities in carrying out the law and encouraged the ravings of the anti-vaccination faddists.

The managers of the Chelsea Hospital for Women have filled up their cup pretty full. The post of anæsthetist was not filled up when the rest of the new staff were appointed, but lately the Board advertised it, and declared a general practitioner ineligible, apparently merely to exclude the officer who had served them for three and a half years without accident or complaint.

Mr. Bland Sutton has accepted the office of surgeon. I feel sorry for this, as I think men of his standing should have refused office under a Board which has behaved so badly to the profession.

The Cork clubs have imported some surgeons, but do not seem very satisfied with the result. It is to be regretted that any young, impecunious man should be tempted to step into such positions. But what is to be expected? Has it not always been so even in important appointments? Whoever heard of men resigning and no one being ready to supplant them? Only this week I heard of an occurrence which shows the estimate Boards have been allowed to form of medical officers. The chairman of a certain Board opposed a request of the staff, and when it was hinted that the staff might resign if refused, he said, "Let the staff resign; there are plenty of doctors would be ready to take their places." That is the fact, and until the profession hold together their services will never be appreciated properly. All honor to the Cork doctors who have stood shoulder to shoulder. Their would-be supplanters should be ostracized professionally and socially.

APPENDICEAL ABSCESS IN THE FEMALE SIMULATING INTRA-PERITONEAL OR TRUE PELVIC ABSCESS.

To the Editor of the Medical Record.

Sir: The interest which the case of premature delivery of a dead child caused by acute appendicitis reported by me in the Medical Record for December 1, 1894, has excited, induces me to ask you to again grant me a small amount of your valuable space for the purpose of relating two cases of unusual interest in the same line. One of these cases I forgot to report in the article mentioned; the other I have seen since that article was published.

In October, 1890, Dr. F. A. Utter brought to my office a girl fourteen years of age, with the following history: First menstruated at twelve, fairly regular since, last menstruation three weeks ago; about eight weeks ago had a fall on the right hip, since then pain in right iliac region; since three weeks a more or less constant offensive discharge from the vagina. No record of temperature. Examination showed the hymeneal opening dilated by a soft, fluctuating tumor, pressure upon which caused a discharge of offensive pus. This tumor extended up into the vagina on the right side and on bimanual examination was found to reach up into the right iliac fossa. A small opening was discovered on the right side of the vagina from which the pus oozed on pressure. A sound passed into the cavity reached as high as the crest of the ilium. Remembering the three cases of a similar nature which I had seen (and which are mentioned in the article referred to) and judging mostly from the localization of the abscess on the right side and from the peculiarly fetid character of the discharge, I pronounced the case to be one of perityphlitic abscess, which had worked its way down on the right side of the pelvis, dissecting up the peritoneum and the vaginal wall until it presented at the vulva. Two days later, at the patient's residence, I enlarged the opening, thoroughly irrigated the cavity, inserted a drainage-tube, and in due time under Dr. Utter's care the patient recovered.

Two weeks ago (February 28th) I was called late in the evening by Dr. Alfred R. Crain to see an unmarried lady who for about two weeks had been ill with what he considered to be pelvic peritonitis. Her temperature had varied between normal and 104° F., the latter being the record when he came for me. Bowels more or less constipated. She had been in considerable pain, requiring frequent doses of morphine, under the influence of which I found her. The abdomen was somewhat distended, and there was dulness extending two-thirds up to the umbilicus in the suprapubic and left iliac region; only slight dulness on the right side. The vaginal canal was almost completely closed by a doughy swelling between rectum and vagina. The nurse having called my attention to a slight, very offensive discharge on the pad which she had just removed, I decided that there must be an abscess in the pelvis, apparently already slightly open, and that it was essential to ascertain where it could be reached and the pus evacuated. As I could with difficulty make a vaginal examination, I inserted my finger into the rectum and at once found a soft, fluctuating spot in the recto-vaginal septum. Pressing my finger against this spot, to my surprise the septum broke and my finger passed into a large cavity, from which a torrent of intensely fetid pus poured over my hand and arm, the amount of which pus can hardly have been less than a quart. The patient at once expressed great relief. On exploring the sexual organs through this cavity I found them to be healthy. The correct diagnosis at once flashed upon me. I then irrigated the cavity thoroughly with a 1 to 10,000 bichloride solution, and advised Dr. Crain to insert a drainage-tube on the next morning, there being none procurable at that time of night. This he afterward informed me that he did, using two tubes. The discharge gradually

ceased, the temperature at once became normal, and the patient made a rapid recovery.

Although the abdominal dulness and swelling were on the left side when I saw the patient, I am confident from the history, and especially from the point of rupture into the rectum and the excessive fetor of the discharge, that this also was a case of retro-peritoneal perityphlitic abscess, similar to the four other cases seen by me. That the uterine appendages were healthy in this last case, I have already mentioned.

To recapitulate: I have seen five cases of appendiceal or perityphlitic abscess, four in the female sex, which developed extra-peritoneally, dissected up the peritoneum and opened into the bowel, three spontaneously, the fourth on pressure by my finger, the pus being discharged per rectum, and rapid recovery ensuing. In the fifth case, the first of the series, the abscess pointed in the median line between umbilicus and pubes, and was there opened by me. In two of the cases the abdominal tumor was on the right side when I saw the patient, in one on the left side, in two in the median line, one of these being a boy, aged fourteen, whom I saw twenty years ago when I still took general practice. The location of the abdominal swelling, therefore, is not a sure criterion that the abscess may not have started in the right iliac fossa and be perityphlitic in its origin. I think that both anatomically and clinically we should distinguish between perityphlitic abscesses which point away both from the anterior abdominal wall and the visceral peritoneum, and show a tendency to burrow behind the peritoneum, whether downward or upward, and those which pursue the usual direction. Surgically, of course, such a distinction can scarcely be made, since it is our object to evacuate the pus as soon as suspected or located, and to remove the appendix when it can be found. And this is the rule and practice in all cases where the abscess remains stationary at its starting-point in the iliac fossa. It is these rare exceptions, of which I have been so fortunate as to witness five instances, which rob the surgeon of his opportunity to do a brilliant operation, and offer nature the occasion to effect the spontaneous cure of a condition which, if the rupture happened to take place into the peritoneal cavity instead of into the intestine, would speedily and almost inevitably prove fatal. Unfortunately, no man can foresee in a case of appendiceal abscess where the rupture will take place, and we cannot risk waiting for the fortunate accident which cured the patient in the cases I have related. Hence, the lesson to be learned from these cases is more one of diagnosis than of practical therapeutics. The old surgical rule to evacuate pus whenever and wherever it is found by the nearest practicable route, still applies with equal force in appendicitis, whether it occurs in the male or the female.

[On March 17th I operated on a case of acute appendicitis during the fifth month of pregnancy, which had been sent to Mount Sinai Hospital by Dr. R. Abrahams, with the probable diagnosis of appendicitis. The patient's illness dated back five days before admission, the symptoms being severe pain in the right iliac region, and a temperature running up to 102° F. On the day of admission temperature and pulse were normal. There had been constipation for six days, but after laxatives given in the hospital there were several free movements. On the day after admission, however, the temperature increased to 102.8° F.; pulse to 120; pain in right iliac region intense; general tympanites. Examination under chloroform revealed distinct dulness and an obscure tumor in the right iliac region. Immediate operation was decided on, and the result proved the correctness of the indication. A large amount of intensely fetid pus was evacuated from a cavity which was partly closed by adhesions of the intestine. The appendix was not found, nor sought for with great care, as it was thought best not to disturb the adhesions. The cavity was packed with iodoform gauze. Result as yet undecided, but prognosis not very favorable on account of probable infection of general peritoneal cavity.]

PAUL F. MUNDÉ, M.D.

20 WEST FORTY-FIFTH STREET, March 9, 1895.

CONSERVATIVE VIEWS OF ANTITOXIN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of December 29, 1894, in an editorial comment on diphtheria antitoxin, you very properly take the stand of a conservative observer, open to conviction, indeed desirous of being convinced, but demanding more facts in evidence. Without doubt, your position expresses the views of the profession at large on this subject. There is an observation among Chicago Board of Trade men, which in the light of recent history expresses the feeling of many medical men. They say on 'Change, "Because a man says he knows a thing is no reason he does know it." This is just the point. Do the antitoxin advocates know what they are talking about, or is a laudable desire making them *post hoc*, not *propter hoc*, observers? Two years ago, all the world, professional and lay, was electrified by the news from Berlin. Koch's "Ich habe es gefunden" for the time became an epochal sentence, everybody got to know all about the tubercle bacillus, and through the efforts of an energetic daily press the laity, and some considerable portion of the profession, came to believe that this special animal had been "knocked higher than Gilroy's kite." The profession is not done yet explaining to an intelligent laity how it got so badly taken in on this subject.

There are certain clinical conclusions with reference to epidemic diphtheria which very much incline practitioners to the editor's conservative demand for more facts in evidence. Some of these conclusions are: That the virulence of a diphtheria epidemic is much greater some years than others, and during some periods of the same epidemic than others; that certain subjects of a strumous diathesis, fair skin, light hair, and blue eyes, fall quickly to the disease; that in rural districts the disease has been observed to be septenary, increasing in intensity from the first to the third year, but comparatively easily controlled at its height, the fourth and fifth or third and fourth years, and declining to types easily managed by any logical treatment from that period to the seventh year.

The statistics which Dr. Roeth gives in the MEDICAL RECORD of March 9th, and which he gathered from personal service on the staff of Dr. Chaillon, in the Hôpital des Enfants Malades, Paris, are of great interest, as are those, this year, of a number of competent observers; but they do not justify the doctor's conclusion, viz., "that a clinical experience showing a decrease to eight per cent. mortality—and this is placing it high—in Dr. Chaillon's wards, is itself a sufficient defence of serum-therapy as applied to diphtheria." Much that enters into the question is: how virulent is the attack, and is it late, early, or at the height of the epidemic that this year's diphtheria statistics are taken?

Aronson, at the Buda-Pesth Congress, announced his mortality at fourteen per cent. in 192 cases. Roux, previous to this, had announced seventy-five per cent. of recoveries: these, with the reports of Dr. Roeth, from Dr. Chaillon's clinic, and that of Dr. Katz's results, noted on page 375, of Vol. 46, of the MEDICAL RECORD, are certainly remarkable, and hopeful to the conservative professional man, if only time will sustain them. Meanwhile we must wait and hope, and while we are doing both there is some diphtheria history it is well not to lose sight of in our enthusiasm, and that is, that the best results of serum-therapy have been equalled and even excelled by other lines of treatment. Aronson's statistics were equalled in the results obtained by the staff in charge, during the epidemic of diphtheria

at the Ohio Soldiers and Sailors' Orphans' Home, at Xenia, O., September, 1889, to April, 1890. The death-rate was fourteen per cent. out of 242 cases. The institution contained during this time nine hundred and thirteen children and one hundred and fifty employees, all housed on five acres of ground. No hospital facilities, with scarlet fever—234 cases—and la grippe—40 cases—running their course at the same time, the treatment developed then has given those who have used it in private practice a mortality of less than ten per cent.

Dr. T. C. Minor, of Cincinnati, in an editorial in the *Lancet-Clinic*, makes some observations which will bear much thought. He says: "Medical statistics should never be too hastily accepted; what do the advocates of Roux think, for instance, of the statistics of Lescure, physician to the Oran Hospital, who cured all his 51 cases of diphtheria with a forty per cent. solution of chromic acid? How about Goubeau, who reported 21 cases of diphtheria cured by corrosive sublimate and glycerine? How about Flatraut, who cured 15 cases with petroleum? A late Paris medical journal publishes a total of 427 cases and only 37 deaths, giving a mortality of a little over eight per cent.; these cases were not subjected to the serum therapy of Dr. Roux." These last statistics would seem to the writer to evidence a mild type of the disease in Paris, at the time they were compiled, a condition likely to give too high an estimate of the value of the line of treatment used at the time. Dr. Minor further observes that "not a single one of Roux's cases but was treated by local application of Labarraque's solution to the throat." A pertinent and permissible query is, Why? The editor of the MEDICAL RECORD has seen too many idols demolished in the past to permit the enthusiasm of hope to take the place of that of fact, and while he is open to conviction, as we all are, he still, in his editorial, expresses the views of a great, even if silent, majority of the medical profession in this country.

WILLIAM A. GALLOWAY, M.D.

XENIA, O.

ON THE PROPER METHOD OF ASCERTAINING THE CHEST EXPANSION BY MEASUREMENT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In my recent paper on "The Influence of the Bicycle in Health and in Disease"[1] I made the statement that the normal chest expansion of the average man is one inch, except in those cases in which the respiratory apparatus has been developed by some special form of exercise. This statement has called forth many letters of protest. I am aware that the results of my investigations are totally at variance with the established opinions relative to the chest expansion of man, but this variance consists solely in the manner in which the measurements are made. Insurance companies and some other corporate and incorporate bodies usually, and in some cases invariably, carefully test the chest expansion of those who propose to join them. Statistics have been compiled from thousands of these measurements and deductions have been published which, when based upon the usual method of measurement, cannot be anything but erroneous.

It is quite unnecessary for me to explain the usefulness of obtaining and preserving accurate records of the chest expansion of thousands of people, both adults and children, and of observing the deviations from the normal standard in certain diseases of the respiratory organs, or of the nerves of those organs or their centres in the cerebro-spinal system. This is admitted, but unless the records express the actual chest expansion, and nothing more than this, they are absolutely useless for any scientific purpose. I may safely venture the opinion that there are very few chest-expansion measurements made by insurance examiners or by the examiners of school-children that even approximately express the truth. The only part of the chest expansion which is of any practical importance is determined by the volume of air which an individual can draw into the lungs in excess of the natural inspiration. The amount of air which is inhaled while the body is at rest is a trivial matter generally, but it is a subject of great importance to know that the lungs should be capable, during vigorous and prolonged physical exercise, of performing their functions in a satisfactory manner. Whether they can do this or not depends, in a great measure, upon the inspiratory capacity of the lungs, and can be relatively determined by measuring the girth of the chest during normal respiration, and then noting the increase of girth when the lungs are filled from this point to their utmost capacity. The usual method of measuring the chest is to permit the person measured to exhale all the air he possibly can and then to increase the girth of his chest by every method at his disposal. But can anyone really believe that the measurements obtained in this way are true expressions of the actual chest expansion? They certainly have no scientific value, because they are not founded upon the truth. They do not even accurately express, relatively, of course, the total capacity of the lungs. A measurement obtained in this manner may conveniently be separated into three parts for the purpose of analysis: 1. The increase in the girth from the point of greatest contraction of the chest (forced expiration) to the normal breathing-point. 2. The increase in the girth from the point of normal breathing to the point of greatest capacity (forced inspiration). 3. The increase of girth from voluntary contraction of the scapular, pectoral, and abdominal muscles. This latter means of increasing the girth of the chest is, I am convinced, greatly underestimated. I have seen many individuals who could, after inflating their chests to the utmost, increase the girth from two to three inches more solely by muscular contractions. This method of increasing the girth of the chest should be carefully guarded against. It is not always a simple matter to do this. Almost every individual is more than anxious to show to what a great extent he can expand his chest, and even when requested not to unconsciously brings muscular contractions in to assist in accomplishing this object. But these muscular contractions, while they increase the girth of the chest, do not in the least degree increase the capacity of the lungs to contain more air. Hence any chest measurement in which the expansion due to inflation is augmented in any way by voluntary muscular contractions is erroneous and of no value whatever.

Taking the measurement of the chest expansion from the point of greatest chest contraction, that is, when the individual has expelled all the air he can from his lungs and has further contracted his chest by muscular effort, is also an element of great error. The measurement from this point up to the point of greatest inflation may, perhaps, indicate approximately, if the quantity of air inhaled was measured, the total capacity of the lungs. But this is a matter of little importance. The question to be considered is what is the lung capacity of the individual beyond his normal requirements? The expansion of a forcibly contracted chest up to its normal condition is not, in the true sense of the word, expansion at all. Expansion begins when an individual, at repose and breathing naturally, begins to inspire air, and it reaches its maximum when no more air can be inhaled. The measurement, therefore, of the increase of girth of the chest from the point of greatest possible contraction up to the point of normal girth has nothing whatever to do with the measurement of the chest expansion, and must be, together with the increase from muscular effort, absolutely excluded. Leaving out these two elements of great error, the normal chest expansion can be ascertained by

[1] MEDICAL RECORD, February 2, 1895.

finding the difference between the girth of the chest during normal respiration and the girth of the chest at the moment of the greatest possible forced inspiration. And any measurement which includes anything else than this is certainly inaccurate.

In measuring an individual, see that the muscles of his shoulders and thorax are relaxed. If at the end of the forced inspiration there is a sudden protrusion of the chest, call his attention to it; tell him not to do it again; and repeat the measurements until you are satisfied that the measurements of muscular contractions are positively excluded. If this is properly executed, the chest expansion of the average man will be found to be one inch.

In arriving at this average, I had the measurements of over two hundred different men placed at my disposal by Physical Director E. J. Giannini, of the New York Athletic Club. The chest measurements in these cases were taken in the manner advocated in this paper. I also measured, independently, over one hundred different men. The average expansion, with the measurements taken in the usual manner, was over four inches, but when taken properly, an expansion much over an inch was rarely seen, unless the individual had developed his respiratory powers by some special form of exercise.

GRÆME M. HAMMOND, M.D.

OBSCENE LITERATURE AND THE PATENT MEDICINE TRADE.

To the Editor of the Medical Record.

SIR: Dr. Jacobi's letter in the MEDICAL RECORD of March 2d made you an easy convert to the propriety of the bill he favors. Presuming that the MEDICAL RECORD and other medical journals have subscribers among non-medical libraries and non-medical men (lawyers or teachers, for instance), it is possible that such a law might entail a good deal of inconvenience upon medical publishers. Perhaps they would be willing to put up with that, however, if Dr. Jacobi's object could be secured by his bill. This is questionable. I am credibly informed that already half a dozen of the most active and pushing patent-medicine concerns that send out circulars concerning sexual diseases enclose all their matter in sealed envelopes, and have done so for a year or more. So, in spite of Dr. Jacobi's bill, the Turkish wafer advertisements might fall into the hands of fifteen-year-old boys. Would it make any difference to the parent of the boy or Dr. Jacobi's feelings in the matter whether the circular is sent sealed or unsealed? The letter of Dr. Charles E. Nammack in the same number of the RECORD presents another aspect of this matter. He speaks of the corrupt influences at work and the unnatural sexual practices sapping the vitals of youth. It is a fair question whether the objectionable circulars referred to would not have far more effect in the way of frightening the youth of the land against bad practices than encouraging them. But further, another and far different class of literature has now come in the field for the direct purpose of wisely warning young folks. They are tracts or pamphlets prepared by physicians and others for the social purity department of the Women's Christian Temperance Union. Perhaps some of them might be found hardly proper for general and indiscriminate circulation. Again, how would Professor Burt Wilder's book, "What Young Folks Ought to Know," fare under that bill, and several other worthy books of the same kind? In proposing any new legislation it is always well to carefully consider whether the probable benefits will outweigh the possible evils. Dr. Jacobi's bill could not accomplish his purpose, while it might be a hindrance or unfair tax on some useful efforts.

244 WEST FORTY-SECOND STREET.

New Instruments.

A NEW METHOD OF CIRCUMCISION.

By PERRY A. McINTOSH, M.D.,

THOMASVILLE, GA.

RECOGNIZING the difficulties in the determination of the amount of tissue to be removed, the uncertainty as to the extent of stretching of the mucous membrane and of the relaxation of the preputial skin, the difficulty of obtaining an even and smooth coaptation of the tissues, and in order to settle the question in the selection of general or local anæsthesia in all operations for phimosis that have come into use, I have been led to devise an operation which overcomes these difficulties and settles the question in favor of local anæsthesia.

The objects of this operation are to promote cleanliness, to cure or prevent disease, and in certain cases to facilitate conjugal relationship. To meet these requirements a prepuce should only cover the corona when the organ is relaxed, and during erection should retract so as to leave no fold above it.

The instruments and material required for this operation are: 1 scalpel, 1 gutta-percha tube (Fig. 1), 2 braided silk cords (No. 8), ten inches long, 1 fine curved suture needle with silk. The tube is a cylindrical barrel, open at both ends, made of vulcanized rubber or gutta-percha, and is of the following dimensions: Length, 5.1 ctm. (2 inches); diameter, from 12.7 mm. ($\frac{1}{2}$ inch) to 3.18 ctm. ($1\frac{1}{4}$ inch), according to the capacity of the prepuce and size of the glans. Thickness of walls, 1.6 mm. ($\frac{1}{16}$ inch). One groove encircles it 3.2 mm. ($\frac{1}{8}$ inch) distant from one end, and another groove 9.5 mm. ($\frac{3}{8}$ inch) distant from the other. The width and depth of the grooves are about 0.8 mm. ($\frac{1}{32}$ inch).

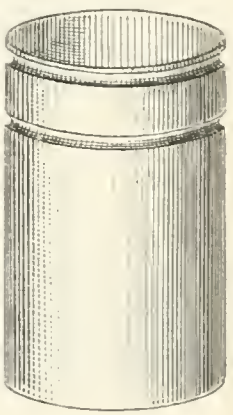

FIG. 1.

The mode of operation is to select a tube suitable to the size of the glans and the capacity of the prepuce. The prepuce is retracted, and the tube is placed over

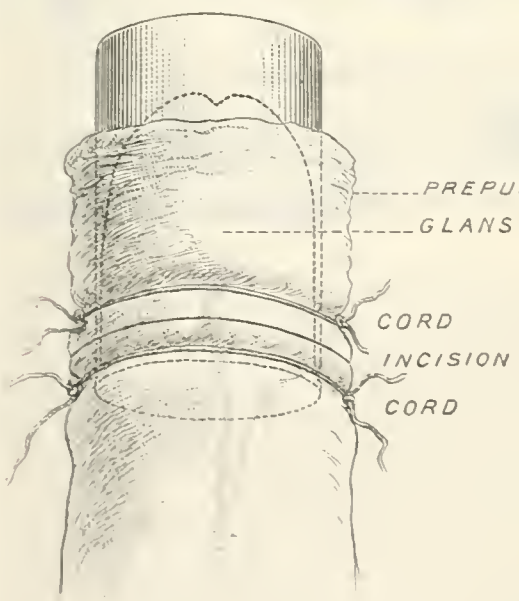

FIG. 2.

the glans and pressed into place till the latter is covered. The end of the tube to be put over the glans is the one with the grooves around it. The prepuce is then allowed to roll down over the tube, assuming its natural

relations to the glans. It should fit about as a glove fits the finger. A cord is carefully tied around the penis over each of the grooves in the tube, so that in tightening them the tissues will be pressed firmly into the grooves.

The tissue between the cords is then cocainized. With the end of the penis held in the left hand a sweep with a bistoury midway between the cords around the penis and down upon the tube is made so as to divide the prepuce. The severed prepuce and the cord which encloses it are removed from the tube. The continuous suture is then made with the cord and tube still remaining *in situ*, the needle entering the cutaneous end coming out through the mucous coat, the tube serving as a stay or guide for the introduction of the stitches. The cord and tube are removed and the wound dressed in the usual manner.

Fig. 2 shows tube in place, cords tied, and line of incision. The advantages of this operation were hinted at in the commencement, and it is not necessary to elaborate them here. There are cases not amenable to this form of operation, such as contracted prepuces which cannot be sufficiently dilated to be placed over the tube.

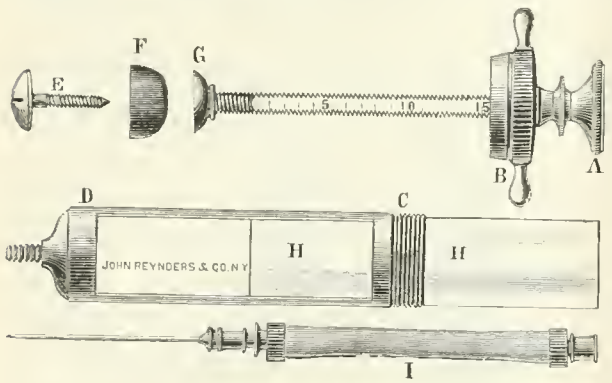
Cocaine, the use of which renders the operation perfectly painless, can always be employed without fear of systematic absorption or local evil effects to the tissue on account of the very small quantity needed to anæsthetize the parts, as the cord partially obtunds the sensibility and prevents absorption.

132 Broad Street.

SOMETHING NEW IN ANTITOXIN AND HYPODERMIC SYRINGES.

Our attention has been called to a syringe wherein the feature of an adjustable piston has at last been solved in an apparently satisfactory manner. Besides this every part of the syringe is detachable and can be put together by anyone not a mechanic.

In the accompanying figure F illustrates the piston,



which consists of a moulded piece of rubber. Its mode of attachment to the piston-rod is readily understood from the parts E, F, G of the illustration. The part D contains a transverse piece, into which the cut-in screw E will catch, when the piston within the syringe is pushed fully forward, and in this position, by turning the piston-rod one way or the other, the rubber piston F will increase or decrease in circumference, so as to fit properly in the barrel H.

The case holding the syringe contains six extra pistons, F, and in less than a minute anyone can insert a new piston when necessary, or when out of them any number can be procured from the makers. This new feature will dispense with the annoyance of having to send syringes away for repair of pistons. The case contains also an extra glass cylinder, which still more readily than the piston can be inserted, and a supply of duplicate cylinders can be had at any time. The illustration is to show an antitoxin syringe of 20 c.c. capacity, but syringes for hypodermic use upon the same principle are also made.

These syringes are manufactured by John Reynders & Co., of this city.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 16, 1895.

	Cases.	Deaths.
Tuberculosis	76	127
Typhoid fever	9	3
Scarlet fever	123	13
Cerebro-spinal meningitis	4	5
Measles	152	18
Diphtheria	201	27

Bacteriological Diagnosis of Diphtheria.—The following are the conclusions concerning the bacteriological diagnosis of diphtheria based on the recent investigations made by Drs. Hermann Biggs, W. H. Park, and Alfred L. Beebe under the direction of the Health Department of the City of New York and officially reported to that body :

"1. All inflammation of the mucous membrane due to the diphtheria bacillus of Loeffler should be included under the name 'diphtheria,' and in this report they have been so included. An acute hyperæmia of the mucous membrane caused by the Loeffler bacilli is considered as truly diphtheria as an inflammation with pseudo-membrane or exudate, and a case in which the lesions are confined to the larynx or bronchi as truly diphtheria as one in which the tonsils and pharynx are involved.

"2. Under pseudo-diphtheria should be included all inflammations of the mucous membranes which simulate true diphtheria and which are due to streptococci, or, more rarely, other cocci.

"3. The name croup or membranous croup should be regarded as a term merely indicating that the location of the pseudo-membranous or exudative lesion is in the larynx, and not as describing the nature of the disease, whether diphtheritic or pseudo-diphtheritic. In New York City at the present time, eighty per cent. of the cases of 'croup' are diphtheria.

"4. The examination of cultures made upon solidified blood-serum under the conditions insisted on by the Department form a reliable method of determining whether the dipththeria bacillus is present or absent in a throat. For diagnostic purposes, cultures should be made before the pseudo-membrane or exudate begins to disappear.

"5. Virulent diphtheria bacilli were apparently in about one per cent. of the healthy throats in New York City at the time of these examinations. Diphtheria, however, was rather prevalent in the city at this time. Most of the persons in whose throats they exist have been in direct contact with cases of diphtheria. Very many of those whose throats contain the virulent bacilli never develop diphtheria. We must therefore conclude that the members of a household in which a case of diphtheria exists should be regarded as sources of danger, unless cultures from their throats show the absence of diphtheria bacilli.

"6. The bacilli found in the original serum cultures, which in appearance and staining are identical with the typical Loeffler diphtheria bacillus, may be regarded, for diagnostic purposes, as virulent diphtheria bacilli, if the cultures have been made either from throats

containing exudate or from those of persons who have been in contact with true diphtheria, for investigation has shown that over ninety-five per cent. of such bacilli are virulent.

"7. All bacilli which are identical with the virulent Loeffler diphtheria bacillus, morphologically, biologically, and in staining by reagents, should be classed with the diphtheria bacilli, whether they have much, little, or no virulence when tested in guinea-pigs. Bacilli which have entirely lost their virulence rarely, if ever, regain it. They probably are incapable of causing diphtheria, for the twenty-four cases in which they were found by us never developed any lesions, nor were they the origin of any case of diphtheria, so far as could be ascertained.

"8. The name pseudo-diphtheria bacillus should be regarded as applying to those bacilli found in the throat which, though resembling the diphtheria bacilli in many respects, yet differ constantly from them. These bacilli are rather short and are more uniform in size and shape than the Loeffler bacillus. They stain, as a rule, equally throughout with the alkaline methyl blue solution and produce alkali in their growth in bouillon. They are found in about one per cent. of the healthy throats in New York City, and seem to have no connection with diphtheria. They are never virulent.

"9. One or more varieties, both of streptococci and other forms of cocci, exist in the great majority, and possibly in all, of the healthy throats in New York City. Cultures from the throats in cases of pseudo-diphtheria contain more cocci, especially more streptococci, than those from healthy throats, but otherwise do not seem to differ.

"10. The investigations of the Health Department have given striking evidence of the marked difference in mortality between true and pseudo-diphtheria, for while it was twenty-seven per cent. in diphtheria, it was under two per cent. in pseudo-diphtheria.

"11. The combined clinical and bacteriological investigation of over five thousand cases has demonstrated clearly the fact that many of the less characteristic cases of diphtheria and pseudo-diphtheria are so similar in appearance, symptoms, and duration that it is impossible to separate them, except by bacteriological examinations. In the more severe cases and after the disease has fully developed, cultures are less necessary, although their systematic use is desirable.

"12. Persons who have suffered from diphtheria should be kept isolated until cultures prove the bacilli have disappeared from the throat, for not only are the bacilli which persist in the throat virulent, but they are not infrequently the cause of diphtheria in others. Where cultures cannot be made, isolation should be continued for at least three weeks after the disappearance of the membrane, for our experience has shown that it is not unusual for the bacilli to persist this length of time.

"13. In pharyngeal cases in which thorough irrigation of the nostrils and throat with 1 to 4,000 bichloride of mercury solution has been practised every few hours, the bacilli have not remained in the throat for as long a time after the complete disappearance of the pseudo-membrane as when no antiseptic has been employed. Other cleansing and antiseptic solutions are also useful.

"14. Inflammations of the mucous membranes due to streptococci, either alone or associated with other cocci, are usually mild in character. These inflammations may be more serious when the lesions are located in the larynx, or when they are complicated by scarlet fever or measles.

"15. While the streptococci and perhaps other forms of cocci may be considered as the primary etiological factor in pseudo-diphtheria, yet, in the majority of cases at least, certain predisposing factors, such as exposure to cold or other deleterious influences or the presence of certain infectious diseases, appear to be of great importance in determining the occurrence of the disease.

"The streptococci which under these conditions apparently cause the disease are probably those which had for a long time existed in the throat, and not those freshly derived through communication with other cases of pseudo-diphtheria. In a small number of cases, indeed, the histories suggest a direct communication, but the causation may be equally well explained by the supposition that the second case shared with the original one the same predisposing cause.

"16. The slight mortality and the usual mildness of the cases of pseudo-diphtheria do not warrant us in enforcing isolation, even if further investigation produced positive proof that this disease is directly communicable.

"With the results of these investigations before us, we can appreciate the difficulty of exterminating diphtheria from a city like New York. On the one hand, we have cases of diphtheria scattered all through the city, many of which are so mild as to be unrecognized, and, on the other hand, we have the crowded tenements with their ignorant and shifting population, where proper isolation of the patient from other members of the family, or of the family from other inmates of the building, is usually impossible unless harsher measures are adopted than are now customary. With stricter isolation of patients and intelligent and systematic supervision of the schools and tenements, we can certainly reduce the number of cases of diphtheria in the city, but the total extermination of the disease under the existing conditions of life here does not seem probable unless we can acquire new means to combat the disease."

Billroth on an International Language.—In a letter written shortly before his death to Dr. Jankau, Professor Billroth expressed himself as follows upon the choice of an international language: "I would recommend the most simple of the Romance languages, that is Spanish, as a common speech for the learned; after that would come Italian and French, and among the Germanic tongues, English only. The latter would be by far the most suitable of all, for it is also one of the simplest. But as the Latin races are so absolutely without the talent for learning foreign languages it is necessary, because of their other great attainments in the line of culture and science, to make a concession to them in this regard, and select a Romance tongue as the international language."

The Rome Congress.—The first volume of the Transactions of the International Medical Congress held in Rome a year ago is now ready for distribution by the firm of Rosenberg & Sellier, of Turin. The members do not receive it free as they did in former Congresses, but are called upon to pay twenty-five cents postage on each volume in advance, otherwise they are informed they will not get the Transactions.

Students in German Universities.—The total number of students in the German universities is 28,158, as compared with 27,646 a year ago. Berlin comes first with 5,031, then follow Munich, 3,475; Leipzig, 2,928; Halle, 1,539; Bonn, 1,518. Würzburg has 1,347; Tübingen, 1,165; Heidelberg, 1,028; Strasburg, 949; Göttingen, 894; Jena, 635; and Rostock, the smallest number, 420. Of the total, 26,008 are Germans, 1,594 from the rest of Europe, and 556 from other parts of the world. Theology claims 4,484; law, 7,432; medicine, 7,768, and philosophy and science, 8,470.

The Physique of the British Soldier.—Physical deterioration has been increasing steadily in the British army in the last twenty years. In 1875 there were only sixty-five soldiers in a thousand under five foot five; last year there were one hundred and twenty-seven. The six hundred and eight in a thousand measuring less than thirty-seven inches round the chest has grown

to six hundred and eighty-five. The proportion of enlisted men under twenty years of age has increased from ninety-seven in a thousand to one hundred and seventy, while that of men over thirty has decreased from three hundred and forty to eighty-eight in a thousand.

Dr. Winslow's Treatment of Homicidal Mania.—Apropos of a number of cases of apparently causeless stabbing in the streets of London, Dr. Forbes Winslow, in a letter to one of the newspapers, made the following recommendation: "In the case of a person who kills another in the street without motive, a certain congestion of the brain and rush of blood take place. If any one were to hit him on the nose, a blow which would cause the loss of blood, it would afford instant relief and he would no longer be actuated by the impulse to murder. These ordinary homicidal lunatics, who are sane on the surface, are the most difficult to deal with. You may talk to them for four hours and they will appear perfectly rational. Yet they will suddenly go out and attempt to kill the first person they meet. The typical homicidal lunatic, unlike the man who is afflicted with a desire to commit suicide, is incurable." He adds that the number of homicidal lunatics at large in London is greater than usual and that he is frequently visited by madmen who are unaccompanied, some of whom want to kill him, others ask to be prevented from killing others.

The Criminal's Eyes.—A law journal published in Russia gives some interesting data collected at the eighteen anthropometric stations in the empire. One of the curious things brought to light is that in Russia each group of criminals has its own particular color of the eye. Thieves and murderers, it seems, possess "chestnut-brown" eyes. Robbers—that is to say, thieves in a large and violent line of business—have slate-colored eyes, and the same is stated of criminals convicted of swindling. The vagabond classes, among whom are probably reckoned the passportless class, have eyes of an azure blue tint. The color most observed among minor criminals and those convicted of slight offences is "chestnut brown-green."

The Chemistry of Cleanliness.—*Nature* publishes an article that proves the virtues of cleanliness to be more than æsthetic. The sudoriferous glands perform the important function of throwing off the moisture produced during the combustion of waste tissue by the oxygen of the blood, and secrete about twenty-three ounces of perspiration in twenty-four hours. This evaporates without producing any sensible moisture of the skin; and is a process for regulating the temperature of the body. The conversion of perspiration into vapor renders latent an enormous amount of heat and keeps the body in a state of comparative coolness. Water at 120° is almost unbearable; but heat in an oven to the extent of 325° may be borne for a time. In the twenty-three ounces of perspiration secreted daily there is about one ounce of animal matter. This is left behind on evaporation. Sebaceous glands also secrete oily and resinous substances. This, mixing with the solid matter and dirt, forms a compound which tends to clog the pores of the skin. The removal of this compound is largely the source of the feeling of refreshment and *bien aise* following a vigorous morning bath.

The Tientsin Red Cross Society's Expedition to Port Arthur.—When the news of the fall of Port Arthur reached Tientsin on November 24th, Dr. B. C. Atterbury and Mr. C. D. Tenney, acting for the Tientsin Red Cross Society, proposed to the Viceroy, Li Hung Chang, that a steamer should be sent to Port Arthur under the auspices of the Society, in order to offer to render assistance to the Japanese Field Hospital Staff in tending the wounded, and, if permitted to do so, to bring a number of the Chinese wounded to Tientsin for treatment. The Viceroy responded most cordially to this suggestion, and placed the Chinese steamer Toonan at the disposal of the Society. The Toonan arrived at Port Arthur at daylight, November 28th. Two Japanese war-vessels were anchored outside the port, the Omi Kan and the Hi-yei Kan. The Toonan approached flying the Red Cross flag and the flag of truce at the fore-mast. The Omi Kan signalled the Toonan to come to anchor, and soon after sent a crew of marines and two lieutenants on board. The object of the expedition was explained to the two officers, and it was arranged that the Toonan should follow the Hi-yei to Ta-lien-wan, to lay the case before the Admiral, who was then at that place. Unfortunately the hoisting-gear broke after a few turns, so that the anchor could not be raised except by tackle; and, as a gale of wind was blowing, it would have taken several hours to have raised it. The Toonan accordingly remained at anchor under the forts at Port Arthur for two days, at the end of which time the commander-in-chief of the Japanese forces sent word that the wounded were prisoners and could not be carried to Tientsin, and that the Japanese surgeons were able to attend to all, Japanese and Chinese alike. So the members of the Red Cross returned with the thanks of both sides for their good intentions, which the rules of war forbade their carrying out.

The English and the American Poets of Hospital Scenes.—Tennyson's description of a scene in a hospital is often quoted because of its poetry, its unpleasantness, and the nasty hit he gives to Dr. Fagge. An American poet, Walter Whitman, has described a hospital scene with superb power and with no personalities. In comparison, Tennyson's work is as the flutter of the bird to the majestic roll of the sea. Read it and believe:

Our army foiled with loss severe, and the sullen remnant retreating
Till after midnight glimmer upon us the lights of a dim-lighted building,
We come to an open space in the woods, and halt by the dim-lighted building.
'Tis a large old church at the crossing roads, now an impromptu hospital.
Entering but for a minute I see a sight beyond all the pictures and poems ever made,
Shadows of deepest, deepest black, just lit by moving candles and lamps,
And by one great pitchy torch stationary with wild red flame and clouds of smoke;
By these, crowds, groups of forms vaguely I see on the floor, some in the pews laid down.
At my feet more distinctly a soldier, a mere lad, in danger of bleeding to death (he is shot in the abdomen).
I stanch the blood temporarily (the youngster's face is white as a lily).
Then, before I depart, I sweep my eyes o'er the scene, fain to absorb it all.
Faces, varieties, postures beyond description, most in obscurity, some of them dead;
Surgeons operating, attendants holding lights, the smell of ether, the odor of blood,
The crowd, oh, the crowd of the bloody forms, the yard outside also filled,
Some on the bare ground, some on planks or stretchers, some in the death spasm sweating,
An occasional scream or cry, the doctor's shouted orders or calls,
The glisten of the steel instruments catching the glint of the torches.
These I resume as a chant. I see again the forms, I smell the odor,
Then hear outside the orders given, "Fall in, my men, fall in!"
But first I bend to the dying lad, his eyes open, a half smile gives he me;
Then the eyes close, calmly close, and I speed forth to the darkness,
Resuming marching, ever in darkness marching, on in the ranks,
The unknown road still marching.

In Four States.—An old doctor had been called to see a drunken man who had been run over by the cars, and upon answering a good many questions he became angry, and said, "I found the man in four different states: the state of intoxication, the state of mutilation, the state of unconsciousness, and the State of Ohio."

THE TREATMENT OF THE DIFFUSE FORM OF SEPTIC PERITONITIS OCCURRING AS A RESULT OF APPENDICITIS; WITH CASES.[1]

BY CHARLES McBURNEY, M.D.,

SURGEON TO THE ROOSEVELT HOSPITAL.

THE cases of appendicitis accompanied by some degree of peritonitis are, of course, exceedingly numerous, for the list includes all of those in which the inflammatory process has reached the peritoneal investment of the appendix itself. The exact extent which the peritonitis has reached in any given case cannot be determined by the gross appearances, excepting in those cases where a limiting wall of inflammatory adhesions forms a perfectly distinct separation between the inflamed and the non-inflamed peritoneum. For practical purposes, however, many cases may be divided into two classes: First, those in which suppuration, great or little, has occurred, and in which the septic process is completely shut off from the general peritoneal cavity by the formation of a distinct inflammatory wall of adhesions. Secondly, those in which this protecting wall is either entirely absent, or more or less incomplete.

This latter class is the one to which this paper refers. At the same time I have excluded from consideration those cases operated upon at such an early stage in the disease that, although a complete separation from the general cavity did not exist, the septic process had extended only over the peritoneum in the immediate neighborhood of the appendix. Such cases yield to operation almost without exception, as do the complete abscess cases even when the abscesses are very large and old.

The cases illustrating the diffuse forms are those in which no adhesions exist, or in which these are so incomplete as to allow the peritonitis and its products to rapidly extend either upward toward the liver, or among the small intestines toward the median line, or downward into the pelvis, or in all three of these directions at once. The pelvis seems to be especially the seat of election for the beginning of the diffuse form, doubtless on account of its dependent position and its relation to the situation of the appendix. The overflow of the septic fluids from the neighborhood of the appendix into the pelvis has seemed to me to be clearly the manner in which diffuse peritonitis begins in a large majority of the cases. Such overflow having taken place, an inflammatory boundary of adhesions scarcely ever forms so as to confine the process to a limited portion of the pelvis, but the peritoneum of the entire pelvis becomes very rapidly inflamed and a very septic, sero-purulent, thin exudation accumulates until the pelvis is full.

A few hours suffice for the fluids to overflow the pelvis and to carry the infection far and wide among the intestines. In a few cases where the accumulation of fluid about the appendix has been excluded from the pelvis by a wall of adhesions, the overflow and spread of peritonitis has taken place in another direction, as upward, or inward and upward.

An interesting question is the one as to why, in one case a huge abscess can form and grow for days and even weeks without breaking down its thick barrier of adhesions, and in another case not a single adhesion form and the inflammation and its products spread rapidly throughout the entire abdomen.

It has seemed to me that individual susceptibility to sepsis is an important factor in determining the progress of the disease, and that if deep infection of the tissues takes place early the protective or reparative formation of adhesions does not occur, or at best occurs very imperfectly. Perhaps also the intensity of the septic quality of the inflammatory products in one case may be very much greater than in another.

Another difference which I have noted is this: If some attempt at the formation of a protecting wall of adhesions is present, even if the pelvis is full of sero-purulent fluid, the prognosis is better than in a similar case where no adhesions of any kind are found, as though the presence of adhesions measured the degree of septic infection of the individual. And where the fluids effused have had a large admixture of thick pus, and the intestines have been more or less covered with thick, yellow lymph, even when the pelvis has been full of fluid and few adhesions have existed, the results have been much better than when the fluid has been merely turbid.

Up to two years ago I had regarded all these cases of diffuse peritonitis as nearly hopeless, although, to be sure, an occasional case recovered after operation, removal of fluid, and thorough drainage. I remember that I once made the statement that we could hardly expect any such case to get well, because before the operation was done the individual had already become so septic as to be beyond the reach of surgery. But I had made the attempt, and in many instances, and had made use first of one and then of another method of procedure. The earliest plan was this: An incision about four inches long was made in the right linea semilunaris, and the appendix was sought for and removed. The fluids in the immediate neighborhood of the appendix were sponged away. Then the spaces between the intestines were syringed out with a very weak solution of bichloride, one or more rubber drainage-tubes were introduced, and gauze packing placed carefully about the stump of the appendix. On one occasion I made a supplementary median incision to facilitate cleansing the cavity, and once or twice I put in extra drainage-tubes on the left side or in the loin. All the cases of extensive diffuse peritonitis treated in this manner died. I then made use of Thiersch's solution for washing the cavity, and endeavored to make the process more complete by using very long and large glass nozzles which could be passed to either hypochondriac region or down to the floor of the pelvis. As no better success followed this plan, I gave up the washing, fearing that the fluid introduced merely carried the sepsis more widely through the peritoneal cavity, and made use of dry sponging, endeavoring to remove every particle of fluid. I cannot say that a single case where the whole pelvis was involved and full of sero-purulent fluid, got well under this method of treatment.

In the meantime I had gradually nearly given up, as others had done too, the use of rubber drainage-tubes in treating suppurating spaces in the peritoneum. Introduced at random among the intestines a tube of any kind has little or no value. The intestines fall directly

[1] Read before the Practitioners' Society of New York.

around it, even plugging the end and lateral openings, and no drainage of value takes place. One exception should be made to this statement. When a tube with a firm wall, such as a glass one, is passed to the very bottom of the pelvis, all fluids that occupy the pelvis will find their way into the tube, for the fluid gravitates to the bottom, and as the intestines tend by their weight to occupy the same space the fluid naturally escapes into the tube. Here it can be mopped out or even drained out continuously by a strip of gauze within the tube. The best drainage in all parts of the body is the capillary drainage obtained by using absorbent dry material like gauze, and the more completely this material touches every point from which it is desirable to extract moisture, the more perfect will the drainage be. My attention was then called to the different effects produced upon the peritoneum when washing it with different fluids, but I am unable to say to whom belongs the credit of having first made the observation. It is well known, however, that the weakest bichloride solution, Thiersch's solution, even hot sterile water, have a destructive effect upon the endothelium of the peritoneum. That is to say, the use of such fluids, while they serve to wash away septic material, tends to cripple the absorbing power of the peritoneum itself.

No plan of treatment which could in the least degree deprive one of the valuable service of the peritoneum as an absorbing agent, could be entirely satisfactory. I therefore turned to normal salt solution used at or above the body temperature, the same solution that was recommended long ago by Thiersch as most perfect for skin-grafting. This fluid, used hot and sterile, and of a uniform strength, six parts per thousand, has little or no destructive effect upon the peritoneal endothelium. The same is true of its application to other delicate tissues, so that in open suture of the fractured patella, for instance, the joint may be thoroughly irrigated and closed, and almost no adhesion of the serous surfaces to one another will follow. It is probable that no actively germicidal fluid can be introduced with safety into the peritoneal cavity, of sufficient strength to be of value in directly destroying the toxic products accompanying a septic peritonitis. What we may endeavor to accomplish is to completely remove the primary source of the sepsis, to more or less thoroughly wash away the secondary products, and to drain away quite completely the fluids left behind and those of post-operative formation. What we cannot accomplish by these means, must be accomplished by the eliminative powers of the individual, and here the integrity of the peritoneum as an absorbing agent is most important. When a case is met with, where septic material sufficient to kill has already been absorbed by the individual, the means that I have spoken of will be of no avail. We may wash and drain to absolute perfection, but our labor in this direction will be useless Possibly the future has in store for us an antitoxin which will accomplish what now seems hopeless.

In the cases which I bring forward to-night, the following plan has been adopted with almost no variation. The incision has been large, from four to five inches long, and has been made as near to the anterior spine of the ilium and the outer part of Poupart's ligament as possible. After opening the peritoneum every effort has been made to remove at once with sponges all fluids in view. Then the appendix has been sought for, removed, and the stump cauterized. The character of the case has, of course, by this time been appreciated, and the fact noted that either no adhesions have existed, or that they were imperfect, or having existed, that they have given way under the pressure of the fluid they restrained ; in other words, that the abscess has ruptured into the general peritoneal cavity. Search has then been made for further collections of fluid, the pelvis being usually examined first, unless this has been clearly walled off by adhesions. Rarely have I deliberately broken such wall, and only when tenderness at another point, or other sign, has led me to suspect secondary formations. In most of the cases, the pelvis has been found more or less filled with a sero-purulent, often offensive, fluid. Where such collections exist, the peritoneum on the intestines is always unnaturally injected. Then cautious search has been made in other directions for similar fluid accumulations. That is, a small sponge on a handle has been carefully pushed first in one direction and then in another, and closely examined for the presence of fluid. When all purulent or sero-purulent products have been as thoroughly sponged away as possible, the washing process is begun, sterile salt solution of the uniform strength of six-tenths of one per cent. being used as hot as can be comfortably borne by the hand of the operator.

In the cases reported only one method of performing the washing has been employed. The solution has been poured from a pitcher or glass flask so as first to fill the pelvis. This has been sponged out rapidly and then a fresh supply poured in, and so on until the fluid returned perfectly clear. At the same time I have used an ordinary operating sponge on a long handle, very much after the manner in which the piston of a pump works, rapidly and vigorously pumping up and down from the bottom of the pelvis to the wound. When the solution returns perfectly clear the same washing has been made in the right loin, and then in any direction where septic fluid has been detected. Finally, the pelvis has been sponged as dry as possible and a long glass drainage-tube with lateral openings passed to its very bottom, a piece of gauze for drainage passing through the tube from one end to the other. A single strip of iodoform gauze has usually been passed close beside the tube and also to the bottom of the pelvis. If the loin has been suspected and washed, iodoform gauze is passed upward outside of the colon as far as the kidney. If the general cavity toward the median line, or beyond, has been involved, the packing is introduced in strips from three to six inches beyond the wound in various directions among the intestines. Finally, the large wound surrounding the stump of the appendix has been widely packed with gauze—no suturing of any kind being attempted—over all a large mass of dry sterilized gauze and cotton is bound with a firm, broad binder.

In the after-treatment a stimulating enema containing from a half-ounce to one ounce of whiskey or brandy is administered, and also a hypodermic injection of morphine and atropine. The stomach is not made use of until quite able to bear fluid food, nutrient and stimulating enemata being sufficient for one or two days if necessary. The glass tube in the pelvis is tested and swabbed out every few hours at first, until found to be dry, and is usually removed at the end of twenty-four or thirty-six hours, a single strip of iodoform gauze taking its place. The change of the outer dressings is made if any sign of saturation is noted, but the deep wound packings are not removed for three days. Even then it is often too painful and difficult to remove the deepest and longest gauze masses, and these may be left in when necessary for five and six days. The active drainage that these have effected is seen in the dry appearance of the spaces left behind. The second packing is very much reduced in quantity, none of the spaces being so widely and deeply packed. Often, to relieve flatulence a large soap and water enema is given at the end of twenty-four hours, and if no results follow this is repeated. Only in case enemata are totally ineffectual is recourse had to laxatives. In that case ¼-grain doses of calomel every hour, followed by a saline at the end of six or eight hours, are my preference. Sufficient morphine is given to moderate continuous pain.

In the cases that have recovered, the effect of the operation and washings has been immediate, the temperature being reduced at once to nearly the normal standard, and not rising again noticeably unless second-

ary abscess has formed. In the cases that have not recovered, a temporary lull of a few hours only has been noted, and then all the signs of septic peritonitis have rapidly returned and increased.

In regard to the symptomatology of the class of cases reported, I may say that the character of the case has usually, but not always, been appreciated by the widespread tenderness, high temperature, rapid pulse, increased vomiting, and positively ill look of the patient. In some of the cases, the signs have been only those of ordinary well-localized suppurative appendicitis. The cases reported are all of those of the diffuse form upon which I have operated during the past two years up to the present date, and also all of those operated upon by my assistants at the hospital. The number of cases is 24. Of these 14 recovered and 10 died. Besides these quite a number of others have been brought to me for operation, or I have been called to them, and found them in too hopeless a condition to justify interference.

Case I.—Miss S. M——, aged twenty-two, patient of Dr. John A. Wells, of Englewood, N. J. Primary attack. This patient's illness began on the morning of May 11, 1893, with very moderate symptoms, which did not prevent her from walking to her physician's office for advice. The usual history of increasing disease followed, and on the following evening Dr. Wells strongly urged operation, although the disease was clearly localized and the temperature was only 100° F. A sensitive tumor of moderate size could be felt in the right iliac fossa close to the iliac spinous process. At about or after midnight there was sudden accession of very severe pain, accompanied by great prostration, vomiting, and the disappearance of the tumor. The patient was seen by me at about six o'clock on the following evening, having refused, up to that time, to entertain the advice to allow operation. All the signs of general septic peritonitis existed. The face was dusky and the expression anxious. The pulse-rate was 130 and the temperature, 103.5° F. The abdomen was greatly distended, discolored, and very tender at all points. Vomiting was frequent and black. The patient was in great distress, with rapid respiration, but her mind was clear.

On May 13, 1893, with the assistance of Dr. L. W. Hotchkiss and Dr. John A. Wells, operation was done at 7 P.M., a very unfavorable prognosis being given. A large quantity of thick pus with abundant admixture of sero-purulent fluid escaped as soon as the peritoneum was opened. A large sloughy orifice existed in a much diseased appendix, which was removed. In the immediate neighborhood of the appendix were several ounces of thick pus. Above and toward the median line a well-defined and perfect abscess-wall existed. This wall had evidently been perfect below and had given way, so that a larger communication with the pelvis and general peritoneum existed. The pelvis was full to overflowing with sero-purulent fluid, very turbid, and the intestines highly injected, and here and there covered with broad layers of lymph, but without adhesions. This description of the pelvis applies also to every portion of the general peritoneal cavity that we brought into view, but probably the complete abscess-wall at the upper portion prevented contamination of the upper right half of the abdomen.

The prospect was not encouraging, but the treatment was very thoroughly applied, many quarts of hot sterile salt solution being used in washing. A large glass drainage-tube was passed to the bottom of the pelvis and left there—gauze being inserted within it. The gauze packings were very generous, passing in various directions into the pelvis and among the intestines upward and toward the left side. The wound was very widely packed. Nausea and vomiting were troublesome for days after the operation, but the pulse, temperature, and general signs were satisfactory until the 17th, when, for a few hours the temperature reached 102° F., without assignable cause. On the next day it was 99° F. The glass tube was removed on the 15th, the end of the second day, and much of the dressings changed. Dressings were changed every two or three days afterward. On the 24th, the eleventh day, a chill and high temperature indicated a secondary pus formation, which twenty-four hours later was opened on the inner wall of the original abscess. No other incident occurred, and the patient walked about on the thirty-ninth day after operation. Probably no patient ever received greater care and attention than this one received from Dr. Wells, to whom, indeed, I feel that the successful result is largely due.

Case II.—C. L. J——, feeble and prematurely old, aged sixty-five, patient of Dr. J. B. Knapp. This patient had had three attacks of mild appendicitis during the past year. At one o'clock P.M., on the day before I saw him, the fourth attack began with pain felt in the right iliac fossa. Pain steadily increased in severity. No vomiting occurred. Pain spread rather rapidly over a considerable area, and before operation very moderate distention was noted. The pulse-rate was 96, and temperature 101° F. Operation was done on January 30, 1893, about thirty hours after the beginning of the attack. The caput coli and neighboring small intestines were found markedly inflamed. The appendix was partly gangrenous, and had a large perforation near its base; much purulent lymph exudate was noted on the large intestine. No abscess wall existed, and the pelvis was full of turbid sero-purulent fluid. Thorough washing of the whole pelvis and right half of the lower abdomen was made, and the usual pelvic tube and other packings introduced. Enemata failed and the bowels did not act until the fourth day, after calomel and Rochelle salts. No interruption to recovery occurred, but healing was slow and not finished until three months had passed.

Case III.—F. B——, colored, aged fourteen years, admitted to the Roosevelt Hospital on December 19, 1894. Forty-eight hours ago sharp onset of appendicitis with chill, nausea, and vomiting. During the last few hours the pain has extended to the left side.

On admission the abdomen was somewhat distended and tympanitic. Whole lower half of abdomen very tender. Temperature, 103.2° F. Operation on December 19th. Thin purulent fluid escaped as soon as the peritoneum was opened, and continued to flow from among the intestines. The intestines were reddened and partly covered with fibrin. Some loops appeared to be of a normal color. The appendix was found much diseased and perforated. Much thin, milky pus filled the pelvis. General washing of the whole abdominal cavity was practised, a pelvic tube introduced, and extensive packing made. The shock from the operation was great, but under active stimulation the patient rallied, and has constantly improved up to the present date. His recovery is entirely assured. Long before time of publication this patient had reached complete health.

Case IV.—Wm. H——, aged twelve years; admitted to Roosevelt Hospital on November 28, 1894; primary attack began forty-eight hours ago. Abdomen distended, very tense, and tympanitic. Marked tenderness in right iliac fossa. Temperature, 103.6° F.; pulse, 128.

Peritoneum opened and fresh adhesions exposed between caput coli and iliac fossa. Beneath these a drachm of thin pus was found. Appendix perforated and containing concretion. Pelvis found full of purulent fluid. Usual washing, pelvic tube, and gauze packings. On December 2d the tube was removed and the packing changed. The temperature remained at about 100° F. On December 6th a secondary abscess, containing one-half ounce of pus, was evacuated from between the intestinal coils on the wall of the abscess.

This patient has now, January 4th, entirely recovered.

Case V.—Mrs. C. S——, aged forty, patient of Dr. William B. Anderton. This patient was seen by me with Dr. Anderton at the end of about forty-two hours

from the beginning of the disease, on March 20, 1894. The first day's history was that of mild disease of the appendix. On the second day, pain steadily increased and the temperature gradually rose from 100° F. to 102.5° F. When I first saw the patient the conditions were these: The belly was very large and fat, and moderately distended. Tenderness in the right iliac fossa was extreme, and very marked also over the whole pelvis excepting the left iliac fossa. Operation was done about three hours after consultation, with the assistance of Dr. Anderton, Dr. C. T. Parker and Dr. S. Beyea. Thick pus and a few adhesions were found about a sloughy and perforated appendix. The abscess communicated quite freely with the pelvis, which was overflowing with a very milky sero-purulent collection. The condition seemed to me an exceedingly dangerous one and the prognosis very doubtful. The method already described was very thoroughly applied and very wide packings made. The next day the conditions were practically normal, and with the exception of obstinate constipation and some stomach disturbance, no interruption to recovery followed. Complete healing required some eight weeks.

Case VI.—C. H. W——, aged five. Admitted to Roosevelt Hospital on December 1, 1893. Four days ago sudden onset; abdomen flat, but tender at all points, more especially in right iliac fossa. Very anxious face and ill look. Thin, offensive pus flowed out on opening the peritoneal cavity. The appendix, free and gangrenous, lay in a large cavity, which extended upward to the level of the crest of the ilium, where it was bounded by good abscess-wall. The lower part of cavity was open and communicated freely with the pelvis, which was full of thin, purulent fluid. Usual washing, tube, and packing. Patient did not recover from shock of operation, and died at end of fourteen hours.

Case VII.—George Y——, aged six, admitted to Roosevelt Hospital on July 25, 1893. Sharp onset of appendicitis one week ago. The patient is said to have improved until twenty hours ago, when pain, vomiting, and other signs became much more marked; general expression very bad, abdomen tense and distended, and whole lower abdomen very tender. No tumor can be felt. Operation on July 25th. On opening the peritoneum, thick yellow pus was spontaneously evacuated. The distal half of the appendix was found sloughy and broken down. The intestines were highly inflamed and covered at points with lymph masses; adhesions were very imperfect. The pelvis contained a quantity of yellow pus, and the same fluid escaped from between the coils of intestines. The entire peritoneal cavity was thoroughly washed and drained. The patient did not rally from the operation, and died with a temperature of 106° F. four hours after operation.

Case VIII.—Generoso Pisce, aged thirty-five, admitted to Roosevelt Hospital May 16, 1894. Three weeks ago, pain, chill, sweating, and vomiting. Has been in bed three weeks. Abdomen distended, large tense mass, extremely tender, in right iliac fossa and extending to median line. Abdominal wall rigid, whole abdomen tender on pressure. On opening the peritoneal cavity there was an immediate gush of very fetid, thin pus, which flowed from a large area, and the finger could be passed beyond median line without detecting abscess-wall. Purulent fluid escaped from this direction also. The pelvis and region of the liver were walled off by adhesions. Second incision was made in the left linea semilunaris; a little clear fluid and few flakes of fibrin escaped. Peritoneum found roughened and congested.

This case was perhaps one with a very large and irregular abscess cavity. Packing in both wounds, after washing. Good convalescence followed. Complete recovery June 26, 1894.

Case IX.—C. W——, aged fourteen. Admitted to Roosevelt Hospital October 29, 1894. Sudden onset of disease thirty-six hours ago, with pain, vomiting, and prostration. On admission the temperature was 100° F., and the pulse-rate 100. The abdomen was not distended. The right iliac fossa was very tender to pressure. Operation on October 29th. An abscess cavity containing a much diseased but not perforated appendix was opened, and about two ounces of yellow pus evacuated. This cavity continued down into the pelvis, which contained a quantity of purulent serum. The appendix and masses of inflamed omentum were removed, and the whole pelvis thoroughly washed with salt solution. Glass drainage-tube and extensive packings with gauze were introduced. The first dressing was made on the third day and rapid convalescence followed. The patient was discharged cured on December 5th.

Case X.—G. H. B——, aged fifty, admitted to Roosevelt Hospital December 3, 1894. Attack began with general abdominal pain and vomiting about fifty-four hours before admission. Vomiting occurred only once, but pain steadily increased, with rapid distention of the abdomen and complete obstruction of the bowels. On admission the temperature was 101.5° F., and the pulse-rate 110 and feeble. The tenderness, while general, was most marked over the left iliac fossa; a positive diagnosis could not be made. On opening the belly in the median line the evidences of a general septic peritonitis were at once noted. Few adhesions existed and large quantities of pus flowed from every part of the cavity. The intestines were at every point highly inflamed and largely covered with fibrin. A much diseased appendix perforated by a large concretion was found and removed. Thorough washings and drainage were made, but no mitigation of symptoms followed, and the patient died about twenty-six hours later.

Case XI.—Emily K——, aged eleven, admitted to Roosevelt Hospital April 12, 1894. The attack began four days ago, with the usual signs. On admission, the temperature was 101.6° F. and the pulse-rate 140. The abdomen was much distended, the tenderness general, but most marked in the right iliac fossa. The general expression of the patient was that of severe illness. Operation was done April 12th. At the first incision of the peritoneum, thin foul pus flowed very freely; no adhesions existed, although some fibrinous flakes were seen on the intestines. Free pus extended upward to the liver and filled the pelvis. The appendix was perforated near the base and was removed. The usual washing with salt solution was made and the glass tube and gauze drainage introduced. Patient did not improve after operation and died about twelve hours later.

Case XII.—Daniel B——, aged forty-four, admitted to Roosevelt Hospital December 5, 1893. One previous attack of short duration. Present attack began five days ago with well-marked signs. On admission the temperature was 102° F. The pulse-rate, 130. The abdomen was generally distended, but tenderness on pressure was confined to the right iliac fossa. Operation, December 5, 1893, at 4 P.M. The intestines were found much distended and intensely injected. No separate abscess cavity was found, but free thin pus lay between the coils of gut, and especially next to the wall of the iliac fossa. Some coils were firmly bound together and others were free. The appendix was so tightly bound to a coil of intestines at the edge of the pelvis that it was deemed unwise to dissect it out, and the distention of gut was so great that wide explorations could not be made. Thorough washings with salt solution were made, and large packings with gauze for drainage. This patient made a complete recovery, and was discharged cured on February 2, 1894.

Case XIII.—Franz B——, aged fourteen, admitted to Roosevelt Hospital December 19, 1894. Primary attack beginning forty-eight hours ago. Chill and vomiting. Pain rapidly extended from right iliac fossa so as to include the left side. Abdomen distended and

tympanitic. Tenderness all over lower abdomen. Temperature, 103.2° F. On opening cavity immediate escape of thin purulent fluid. Constant escape of thin pus while handling intestines. Intestines highly injected and largely covered with lymph. Perforated appendix, which discharged pus. Peivis full of very milky fluid, no adhesions. General washing and very extensive packing with gauze among intestines in every direction. Condition at end of operation very feeble, but steady gain after a few hours of constant stimulation. During December 21st, 10 A.M., vomiting. December 23d, much better, large movements. Eighteen days after operation all conditions normal. Complete recovery.

Case XIV.—S. C——, nine years of age, was admitted to the Roosevelt Hospital on December 17, 1894. Primary attack of appendicitis had begun two days earlier. The general expression was very bad, the abdomen was greatly distended, and tenderness was extreme all over the belly. The temperature was 102° F. and the pulse-rate 132; operation was done at once. A very purulent general septic peritonitis existed, fluid being found at every part of the abdomen, and the intestines were highly inflamed. Washing and drainage had no perceptible effect on the symptoms, and the patient died thirty-six hours later.

Case XV.—Nathan H——, aged sixteen, admitted to Roosevelt Hospital on October 6, 1894. Patient's first attack occurred two years ago. The present illness began sixty hours before admission, with sharp onset. On admission the pulse was feeble, and the temperature 103° F. The abdomen was very tense and tender, the thighs were flexed on the body and great complaint of pain was made. Operation was done on October 6, 1894. The intestines were much reddened and covered with fibrin. The appendix was found free and perforated, and surrounded by pus; thin pus escaped from between the coils of intestines. A second incision was made on the left side, and the whole cavity washed and drained. No cessation of the symptoms of septic peritonitis occurred, and the patient died on October 9th.

Case XVI.—John G——, thirty years of age, admitted to Roosevelt Hospital on July 7, 1893. No previous attacks. Present illness seven days old. For last four days, chill daily followed by sweat. Temperature, 102.8° F.; pulse, 130. Abdomen soft; little tenderness excepting over appendix. Operation on July 7th. Abscess cavity close by colon, which extended freely into pelvis, where several concretions and much necrotic tissue were found. July 8th, 10 P.M., temperature, 104.2° F.; pulse, 130. Septic look, moderate tympanites. On July 9th, a second incision on the left side was made and a second washing of the lower abdomen performed. Septic peritonitis was clearly marked, and steadily increased. The patient died on July 9th, two days after the primary operation.

Case XVII.—Edward F——, an adult, admitted to Roosevelt Hospital on November 11, 1893. Sudden onset, less than forty-eight hours ago; severe chill with great pain, vomiting, and prostration. On admission temperature, 103° F.; pulse, 108. Abdomen tense and tympanitic. General tenderness all over the right iliac fossa; appendix gangrenous; intestine injected; abundant free, brown, thin pus. The pelvis found to be full of the same fluid. Thorough washing with salt solution and free packing with gauze in various directions. Condition at end of operation feeble. Temperature steadily rose; vomiting persisted; delirium set in, and patient died at end of about thirty hours.

Case XVIII.—Henry D——, aged twenty-one. Admitted to the Roosevelt Hospital on August 15, 1893. No previous attack. Present onset sudden, two days before, with chill and general abdominal pain, vomiting, and prostration. Temperature, 102° to 106° F.; pulse, 100. Characteristic tender points and pain on pressure over the bladder. Appendix thick and red, with necrotic areas at several points. A little turbid fluid about the appendix. In the pelvis a quantity of purulent serum was found entirely free. The glass tube was removed on the 16th and the conditions seemed excellent in every way. This patient did well until the 26th, when pain returned, vomiting became troublesome, the abdomen became distended, and he died on September 1st with a temperature of 103° F. and a pulse-rate of 150. Doubtless a deep secondary abscess had formed, giving rise to a fresh attack of peritonitis. I regret that I did not again open the abdomen.

Case XIX.—A. H——, aged twenty-two, a patient of Dr. Toms, of Bellport, Long Island. Third day of disease. Well-marked ordinary signs of appendicitis, much pain, and wide-spread tenderness over pelvis; temperature, 103° F. Operation July 5, 1893. Assisted by Drs. Murray and Toms. Appendix with large sloughy opening, much sero-purulent effusion, and very few adhesions. Small intestines, lower abdomen well injected, and pelvis full to the brim of sero-purulent exudation. Large flakes of yellow fibrin on different portions of small intestines. Adhesions few and feeble. All signs immediately improved after operation, but convalescence, though uninterrupted, was slow and required nearly three months.

Case XX.—C. P——, aged fifty, patient of Dr. Toms, of Bellport, Long Island, was first seen by me on June 22, 1893. An attack of appendicitis with the usual signs had begun four days previously. The symptoms had gradually increased in severity, but had become much more aggravated during this fourth day. The general expression was that of decided illness, the pulse rapid and full, the temperature 103° F., the abdomen very tense and tender at all points, more especially over the entire pelvis. Operation was done at once, with the assistance of Drs. F. W. Murray and Toms. On first incising the peritoneum a large gush of thin, turbid, sero-purulent fluid occurred. The appendix was partly gangrenous, and no adhesions of any kind were to be seen or felt. The intestines were much distended and highly inflamed. No thick pus or lymph masses were found. The washing of the cavity was carried out very thoroughly indeed, and the usual packings made. A slight lull in the symptoms followed, but septic paresis of the intestines continued, and death, with all signs of septic peritonitis, occurred at the end of about twenty-four hours.

Case XXI.—A. R——, aged nine years. Admitted to St. Mary's Hospital on February 24, 1893, under the care of Dr. George M. Swift. History of appendicitis of rather mild character of two days' standing. Diagnosis of appendicitis made by Dr. Swift.

At 8 P.M. on the 25th the abdominal pain became suddenly very much increased, spreading over the whole abdomen.

The patient was seen by me at about midnight of the same day, and operation was done at 1 A.M., with the assistance of Drs. F. W. Murray, George M. Swift, and George K. Swinburne. The general expression of the patient was good, the abdomen much distended and tender at all points, the pulse rapid and small, and temperature 102° F. Operation revealed a much inflamed appendix, perforated, and containing a fecal concretion. No adhesions of any kind existed. Scattered collections of yellow pus, and very large quantities of turbid sero-purulent fluid escaped from every direction. The intestines were much reddened, and here and there covered with thick lymph. Very extensive washings with hot salt solution were made throughout the pelvis and general abdominal cavity. A large glass tube was carried to the bottom of the pelvis, and packing with iodoform gauze was made in various directions in the pelvis, in various directions among the intestines, and all about the neighborhood of the wound. I should have mentioned that in this case, to facilitate general washing, a free incision was made in the linea semilunaris on the left side, and packings also

introduced here. At 9 A.M. the pulse was 104 and the temperature 99° F.; no nausea occurred subsequent to operation. The dressings were made every two and three days, and the temperature and pulse remained normal until March 6th, when some abdominal pain was complained of, and the temperature rose two degrees. On March 7th a distinct tender induration was noted just below the umbilicus. I made an incision at this point, evacuating about one ounce of foul-smelling pus from between adherent intestines. After the opening of this secondary abscess, which was due, no doubt, to the overlooking at the original operation of some small quantity of septic fluid, all the conditions became normal and remained so. The wounds were entirely healed on April 17th.

CASE XXII.—Son of F. V. G——, aged fourteen, patient of Doctor W. C. Walser, of Staten Island. Third day of disease, July 20, 1893; highly developed signs of appendicitis, with history of recent marked increase in severity and extent of pain. Temperature, 104° F. General great tenderness over the whole right iliac fossa and over the whole pelvis, excepting the left iliac fossa. Operation July 20, 1893, assisted by Dr. Walser. Abundant thick pus widely spread about the region of the appendix, which was perforated, partly gangrenous, and contained large concretion. Good adhesions above and toward the median line. No limiting wall below, and the pelvis full of very turbid sero-purulent fluid. Intestines markedly injected throughout pelvis. Temperature fell immediately after operation to 100° F., and no subsequent rise occurred. Complete recovery in about four weeks.

CASE XXIII.—Son of G. P. W——, aged fourteen, patient of Dr. W. M. Polk. This patient was seen by me in consultation with Dr. Polk on May 1, 1893. The boy had then been ill, with rapidly increasing signs of appendicitis and peritonitis, for less than thirty hours. The general expression was good, the complaint of pain very great, the pulse rapid, and the temperature 102° F. The abdomen was not much distended, but very tense and tender at all points, though more especially so in the right iliac fossa and over the pelvis. Dr. Polk did the operation, assisted by Dr. C. C. Barrows. I witnessed the operation, and have Dr. Polk's consent to report the case as an illustration of the method I have already described. The incision of the peritoneum gave exit to large quantities of very turbid sero-purulent fluid. The appendix was found directly under the incision, much inflamed, perfectly erect, without adhesions of any kind, and perforated at one point. The washing with sterile salt solution was very thoroughly carried out and large packings with iodoform gauze made. These were not entirely removed until the sixth day, on account of difficulty of detachment. The patient made a rapid and complete recovery without incident.

CASE XXIV.—William K——, aged forty-one, patient of Dr. F. R. McCreery. This patient was admitted to a private room at the Roosevelt Hospital on December 22, 1894, suffering from his first attack of appendicitis, which had begun four days before. On the second day greatly increased pain and severe chill were noted. Since then the pain seems to have decreased; no vomiting has occurred. Operation was done on December 22, 1894. The abdomen was distended but little, if at all. Marked rigidity of the right abdominal muscles existed. The general expression was that of decided illness, the temperature only 100.4° F. and the pulse-rate 88. Great tenderness over the appendix as well as over the whole right flank well into the back. The caput coli was found adherent to the wall of the iliac fossa. The appendix pointed upward outside of the colon. An abscess cavity full of thick pus existed beneath the caput coli and extended upward so as to include the whole right hypochondriac region. The right lobe of the liver was seen bathed in pus. This fluid was also found in front of the intestines as far as the median line. The pelvis contained a large quantity of turbid, purulent, thin fluid, and the intestines, so far as seen, were all injected. The appendix was perforated and contained two concretions. Extensive washing with salt solution was made in all directions where infection was found. One large glass tube was passed to the bottom of the pelvis and a second one upward as far as the liver. Packing with gauze was made upward and downward, and as far as the median line. The subsequent history has been quite uneventful. The dressings were partly changed on the third day, and completely removed and replaced with others on the sixth day. No rise of temperature has occurred and the cavity is now much diminished. To-day, two weeks after operation, all the conditions are normal.

At time of publication of this paper, the patient has long since been out of bed and entirely well with the exception that a single small sinus is not healed.

THE RELATIONS OF MENTAL AND PHYSICAL DISEASE.[1]

BY J. M. MOSHER, M.D.,

FIRST ASSISTANT PHYSICIAN, ST. LAWRENCE STATE HOSPITAL, OGDENSBURG, N. Y.

MR. PRESIDENT, GENTLEMEN: Your selection of vice-president carried with it the double compliment of personal award and recognition of the hospital which it is my honor to represent. The assertion is made that medical officers of hospitals for the insane constitute a special sect, not in touch with the general profession, and that, by reason of their isolation and associations, occupation, and interests, they lack opportunity for the application of the principles of medicine, and are even deficient in the knowledge which constitutes the basis of true scientific work. Frequent repetition of this argument has developed a generally accepted belief, not sustained by the facts. The records of medical societies, local, State, and national, bear ample witness to the work of alienist physicians, whose names are conspicuous, as members or officers, in whatever register we seek. Inbred traditions and intuitions are no less indelibly stamped upon the administration than upon the establishment and organization of hospitals for the insane, which are second to none of the monuments to the humanity, charity, and progress of our profession. Speaking for the St. Lawrence State Hospital, representing your section of the State and situated in your county, the reciprocal relations between the general profession and the medical staff have been from the first most active and cordial, and have resulted in an interchange of opinion and experience inestimably valuable in the study of insanity and its relations with so-called physical disease. The conclusion is inevitable that the distinctions and differences are more apparent than real, and that successful results in the treatment of disease of the brain are attained by pure medical methods no less than in the treatment of affections of any other part of the organism. Mental disease as an entity, whether its manifestation be melancholia or mania, exhilaration or depression, disorder of the will or of the emotions, yields to the preponderating physical depravity, and remains only as a complicating group of symptoms, often, it is true, perplexing and obscure, but subordinate. As the artist's canvas is primed with the tone which is to prevail in the finished painting, that the scene may present the bright glow of spring or summer, the richness of autumn, or the crisp, frosty cheerfulness of winter, so in our cases of physical disease there is the background of insanity, with its multifarious perversions of function, which obscure the plainer symptoms and give an altered tone to the completed clinical picture.

In investigating the interdependence of physical and mental disease, we are confronted by the variety and

[1] The Vice-President's Address, delivered at the semi-annual meeting of the St. Lawrence County Medical Society, October 16, 1894.

richness of the material. The doubt is raised whether a true physical basis of insanity is displayed, or a science of the mental symptomatology of disease is evolved, which now contents itself with the few characteristics of the *spes phthisica*, the anguish of cardiac disorders, irritability of nephritis, or depression of dyspepsia. For discussion of my thesis, I submit cases from the hospital records, with consideration of the results upon the mental condition of changes in the physical health.

The Nervous System.—The mental defects following gross organic lesions of the brain are well known and of obvious origin. Less pronounced are their premonitions. Temporary disorders of the special senses or of speech, transient localized spasm or numbness, vertigo, syncope, or general weakness, are suggestive and threatening, but of greater import when enforced by loss of memory, irritability, or other form of emotional excess, which alone are of no greater value than the rare and almost unexplainable presentiments in the mind itself of its own destruction. Dean Swift was one day found gazing in a solemn state of abstraction at the top of a lofty elm, whose head had been recently blasted by a hurricane, and exclaimed, "I shall be like that tree—I shall die at the top first."[1] And in the journal of Scott, the melancholy anticipation of his own fate, with Swift's end vividly in his mind, is shown in an entry "expressive of his fear lest the anticipated blow should not destroy life, and that he might linger on, a driveller and a show."[2]

In case No. 1054, there was sudden accession of limited and fixed delusions, referrible to disturbance of general sensation, and resulting in grotesque ideas more characteristic of long-developing insanity than of the turmoil and variations of acute mania. The patient, a woman, aged fifty-seven, married, of culture and good antecedents, was admitted to the hospital July 3, 1893. She was said to have been of nervous temperament and to have presented symptoms of insanity for one year prior to admission, but the exciting cause was not known. During the week before admission her mental condition had developed active and destructive mania, with great irritability, self-assertiveness, and the use of objectionable language—all contrary to her general character. She was especially abusive and hostile to her husband, with whom her relations had been of the most affectionate and pleasant nature. About one month after admission she showed exhaustion, fairly rapid in its onset, and at the same time fixed her attention upon the delusion that her legs and the legs of other people were made of straw and wood with "the skin stretched over." She persisted in this assertion, always referring to legs. Later she complained of severe pain in the knees and ankles, more especially the right knee, which appeared slightly swollen but not reddened. She was placed in bed, and immediately developed acute bedsores upon the buttocks and upon the right heel. There were cutaneous hyperæsthesia of both legs, increased reflexes of sole and patellar tendon, with pain on movement. The marked cerebral disturbance manifested by these mental and physical symptoms, suggested disorder of the brain circulation and of approaching apoplexy. The possibility of this latter result was predicted upon these grounds. On August 11th, less than six weeks after her admission to the hospital, and less than two weeks after the grouping of the symptoms described above, she suffered an attack of apoplexy shortly after dinner, and died in twelve hours.

As pre-eminently the type of perverted nervous function, neurasthenia bears direct association with insanity, of which it is a wellnigh universal complication. In chronic cases long past the initial neurasthenic stage, its impress remains in the enfeebled circulation, intestinal torpor, dilated pupils, retarded and benumbed sensations, motor debility, and inactive reflexes. In the genesis of insanity, the departure from health is initiated by the train of neurasthenic symptoms, of which the earliest is the development of pathological from physiological fatigue. The sequence and relations of these manifestations have been shown by Dr. Cowles[1] to be, on the physical side, lack of control of nerve-force, failure of co-ordination, and increased excitability with quick exhaustion; the earliest mental indications are weakness of the faculty of attention and alteration of the bodily feelings, producing a sense of ill-being and of effort. So far the symptoms are those of normal tire, amenable to the relief afforded by usual processes of recuperation. The morbid state follows the grafting upon these symptoms of introspection, retrospection, apprehension, worry and hypochondria, irritability and restlessness, from which the change to suspicion and delusion is but a step. Treatment, often ignoring the superficial signs, is directed to the underlying pathological condition and the restoration of healthy tone, and upon this ground the forces of the practitioner and the hospital physician meet.

Rest is the prime indication. When this may be best secured by withdrawal from sources of irritation, and the novelties of sight-seeing and similar mental stimulation, from the sympathetic and too-fidgety interference of well-meaning but oppressively anxious friends, isolation becomes imperative, often in the hospital. There, induced by routine manner of living, by well-ordered direction of trained nurses, and by nutritious food, properly adjusted in time and quantity for the digestive capacity, improvement is often rapid and permanent. The action of tonic drugs is reinforced by electricity and massage. At a proper moment in convalescence, hebetude is sought to be overcome by the stimulation of carefully regulated diversion, and the physical and mental recuperation to be completed by calisthenics, drives, short walks, and easy games, as croquet and tennis.

Case No. 784.—Woman, aged fifty, widowed, nativity Canada, was admitted to the hospital July 19, 1892. It was stated that three years before admission she had fallen from a window, striking her face, and soon afterward became insane. She was treated in another hospital, improved, and was discharged. Later she became excitable and almost uncontrollable. She was subject to periods of excitement in which she expectorated profusely. She claimed that there was a discharge from the posterior nares, that her tongue "trembled at the root," and that her "jaws rattled;" that she had falling of the womb and pruritus. She had paroxysms of irritability, in which she attacked other people. When examined by physicians, she said she wanted to get married and was flirting with the man in the moon, and the barber's pole; that she had fallen and had struck her womb. She was feeble and emaciated when admitted, and weighed ninety pounds. She remained in bed after admission and improved rapidly during the first three weeks. She was fed liberally and was given a tonic of gentian, glycerine, and iron. The salivation continued, and there was also profuse sweating. She complained of pain and peculiar sensations referred to almost every part. On August 1st she was able to sit up a few hours each day, and to leave her room. She then began to show cheerfulness, her physical symptoms gradually disappeared, and there were no more paroxysms of scolding and delusional excitement. From that time, she improved rapidly, became bright and coherent, and on September 28th she was discharged from the hospital, recovered. From her admission on July 19, 1892, to her discharge on September 28th, she gained in weight from ninety pounds to one hundred and twenty-three, and shortly after arriving home she wrote that her improvement had continued, and that she was still gaining in weight.

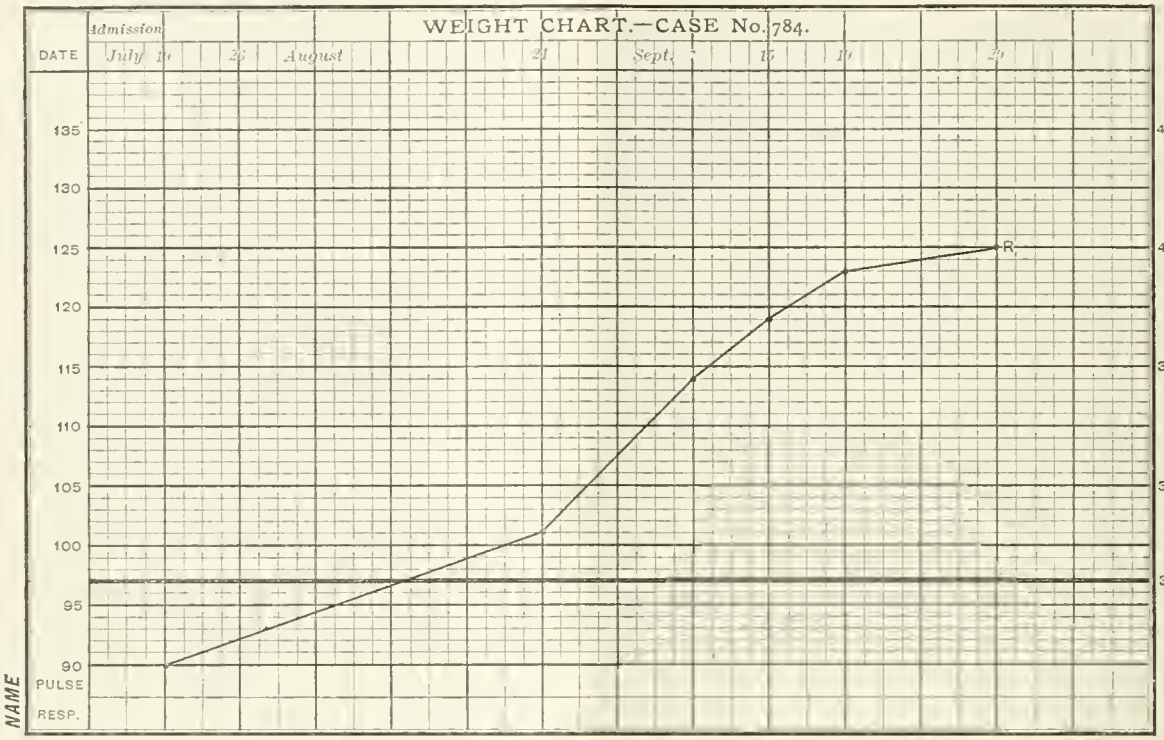
[1] Cowles: Neurasthenia and Its Mental Symptoms. The Shattuck Lecture, 1891.

The Digestive System.—Disorders of digestion are not less frequent complications of insanity than of its associated neurasthenic state. Their correction is essential to successful treatment, and may be expected to exert a prominently favorable effect upon the mental disease. Stomach and intestinal dyspepsia, functional derangement of the liver, constipation and its sequelæ, almost invariably attract attention during the acute stage.



Cases of this class, including those arising from cholelithiasis and intestinal parasites, have furnished substantial grounds for belief in the so-called sympathetic insanities, now gradually yielding to a more exact pathology, which discriminates in degree only between the infantile eclampsia of intestinal irritation and the gradual and more remote reflex of fecal accumulation. Sufficient cause is found in the disturbance of the myriads of nerve-filaments supplying the great expanse of the intestinal tract, and the resulting depravity of nutrition from either impoverishment or contamination. Recovery from acute melancholia following removal of fecal impaction is reported by Dr. Hutchinson,[1] and I have recorded a similar case, in which the same operation was followed by relief of a stuporous melancholia and restoration of the patient to his home and vocation.

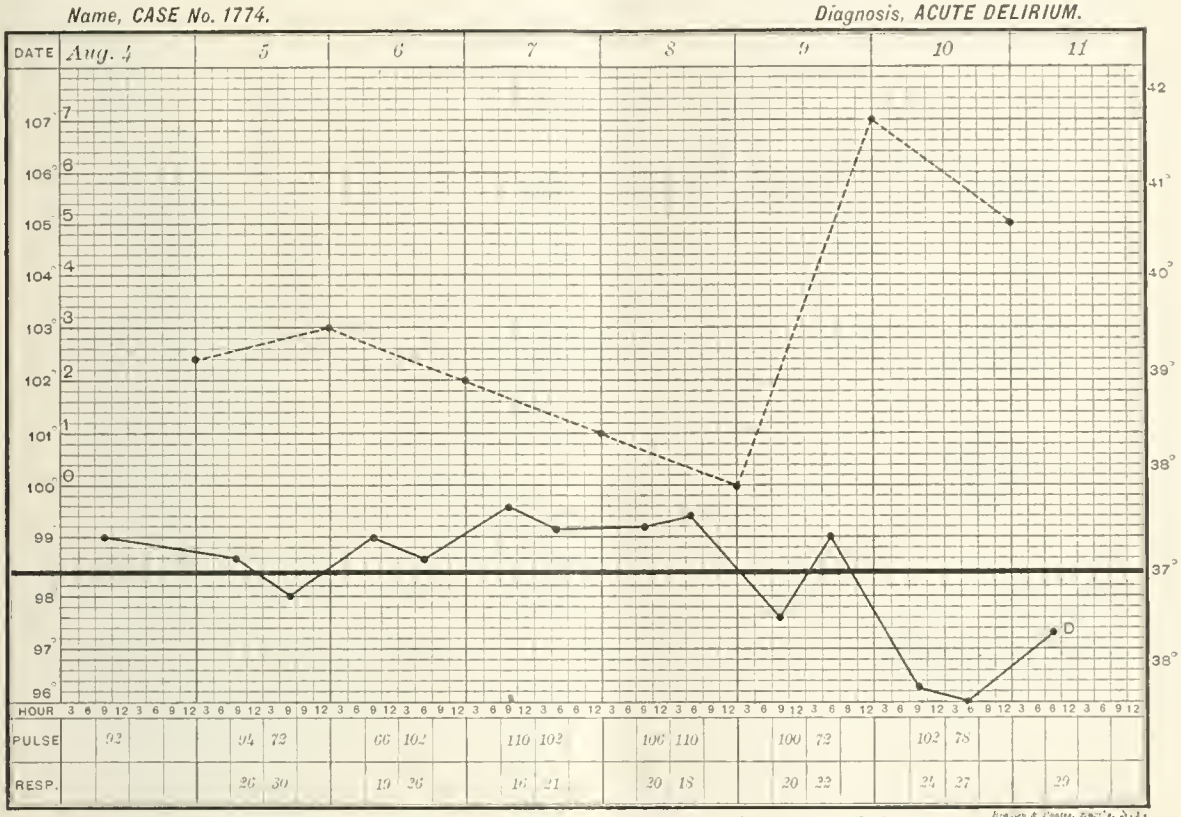
The study of auto-intoxication of the individual from intestinal poisons, throws much light upon the etiology and complications of acute insanity. The ensuing melancholia or mania is active and severe, often with delirium, and followed by rapid emaciation and critical exhaustion. Sunken eyes, dilated pupils, parched and furred tongue, sallow and harsh skin, rapid and weak, irregular pulse, sunken and doughy abdomen, anorexia, constipation, elevated temperature, acute sensibility, unconsciousness, and frenzy reveal the impoverishment of the central nervous system and the dangers of typhomania. Treatment, however prompt and energetic it may be, more often loses than wins. No sedatives with debilitating after-effects are indicated; sulphonal and trional may be cautiously administered; disinfection of the *primæ viæ*, active stimulation and enforced rest, with abundance of easily digested or pre-digested food, may avert the threatening dissolution.

Case No. 1774.—Woman, aged thirty-six, widowed, nativity United States, housewife, was admitted to the hospital August 3, 1894, in a condition of acute delirium. She was said to have been insane for one month, following frequent parturition with ensuing lacerations. The medical certificate of insanity stated that she was restless and depressed, erratic in thought and conversation, had delusions "which appeared to cause her much trouble;" that she talked incoherently and said she had "old stickers" in her legs; that she thought the electric cars were running under the house and she could hear the men shouting to her. Her friends stated that she studied the planets and was constantly busy with her delusions; also, that she did not sleep. At the time of her admission she was notably debilitated, emaciated, and very anæmic. She expressed delusions freely, and they appeared to be based upon active disturbance of the senses. She suffered, at first, quickly recurring attacks of delirium with delusions of persecution and apprehension. Physical examination revealed a feeble, slightly irregular pulse; pale, dry, harsh skin; feeble impulse of heart, without murmur; decided cutaneous hyperæsthesia; dilatation of the pupils; irritable, cracked, but moist tongue, without coating; urine of high specific gravity, with a trace of albumin and a deposit of leucocytes and amorphous urates. The day after admission the debility was profound and the delirious state active. A tonic of iron and strychnine was prescribed, milk punch was ordered, and daily applications of the faradic current were directed. Two days later intractable diarrhœa began and continued, little influenced by active measures for its relief. Three days after admission digitalis was administered every three hours, and attempts were made to control delirium by the hot pack. On the following day nitro-glycerine was administered, in addition to the digitalis, every two hours. At the end of the first week, digitalis, strophanthus, nitro-glycerine, strychnine, and whiskey were administered at hourly intervals in succession, either subcutaneously or by the mouth. On August 11th, eight days after admission and five weeks after the disease was said to have begun, the patient died.

The necropsy revealed intense engorgement of the cerebral vessels with streaks of opacity of the arachnoid membrane, cysts of the choroid plexuses, and softening of the cerebral mass. In the lateral ventricles were patches of reddish discoloration and extravasation in the line of the arborescent vessels. There were tubercular

[1] American Journal of Insanity, vol. xliii., p. 264.

deposits and fibroid tissue in the lungs. The heart contained recent clots and small areas of extravasated blood, but was without valvular lesion. The stomach was dilated and reddened, and the small intestine was injected and contained an abundance of slimy mucus. The kidneys were enlarged and pale, with slightly adherent capsules. Microscopic examination showed cloudiness of the epithelial elements and desquamation of the tufts and tubes, but no diapedesis of blood-cells, the whole presenting the appearance of "acute degeneration," as described by Delafield and Prudden,[1] and



Temperature and Sleep Chart.—Dotted lines showing hours of sleep.

referred by them to the conditions resulting from acute poisoning or inflammations of other organs.

The Circulatory System.—Treatment of organic diseases of the heart and blood-vessels is at the best only compensatory, whether the degenerated valves or non-elastic vascular tubes be affected by the various constitutional affections, rheumatism, gout, nephritis, alcoholism, and syphilis, idiopathic arterial sclerosis, or by the more tardy calcification of advanced age. In frequency of occurrence and the importance of its results, general arterial sclerosis, or arterio-capillary fibrosis, assumes a prominent place, Dr. Wise[2] having recorded ten cases in the admissions of two years to the St. Lawrence State Hospital. The small, firm pulse, with unyielding vessel wall, the forcible and displaced impulse of the hypertrophied heart, and the mental and physical aspect of "premature senility," not rarely escape observation. At the necropsy the vessels yield less readily to the knife, and from the cut surfaces of the kidneys, liver, and brain the elongated and twisted tubes protrude from gaping perivascular canals.

Similarly emphatic are the effects upon the brain of the fluctuations in the blood-current from valvular disease of the heart. Between insanity and the anxious facial expression, sense of impending danger, syncope, and vertigo attending cardiac lesions, the distinctions merely involve questions of diathesis; while upon the mental images of the insane the complicating heart dis-

[1] Delafield and Prudden: A Handbook of Pathological Anatomy and Histology, third edition, p. 403.

[2] Bodily Disease and Senility: a Contribution to the Discussion on the Causation of Insanity, p. 6. Transactions of the New York State Medical Association, 1891.

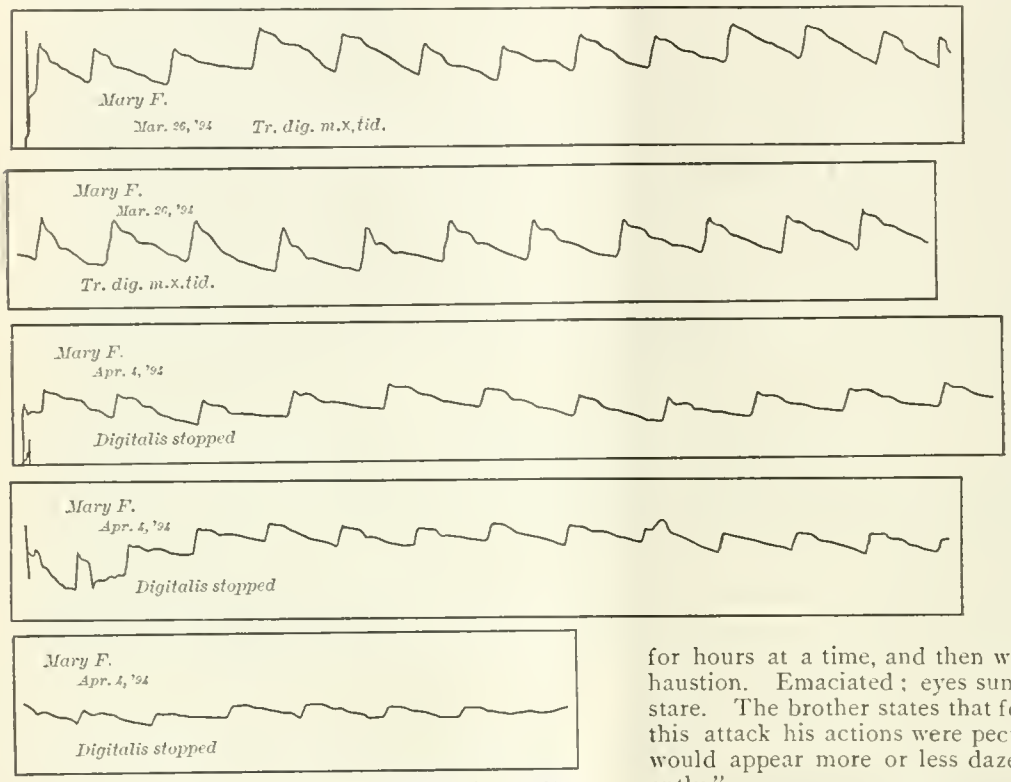
ease throws its shadow and even determines the character of the delusions. Dr. Mickle's[1] analysis shows mitral regurgitation to be most frequently accompanied by depression, with delusions of persecution and suspicion; mitral stenosis with impulsive excitement and discontent, delusions of ill-usage and of poisoned food; aortic regurgitation with loquacity and delusions of exaltation and of internal sensations, such as magnetic influences; and aortic stenosis (often associated with general paralysis) with impulsive violence and delusions of persecution and poisoning. In the following case, of which sphygmographic tracings are shown, temporary benefit followed tonic and stimulating treatment of the heart by the use of whiskey and digitalis.

Case No. 919.—Woman, admitted to the hospital January 6, 1893, aged seventy-one, widowed, nativity New York, housekeeper. Patient was brought from a county almshouse, and at the time of admission expressed ill-defined delusions of persecution, stating that her associates in the almshouse had accused her of following the men out of doors, and that they "twitted and plagued" her. She wept and showed great depression when conversing. The medical certificate of insanity stated: "Said that she hears voices during the night charging her with being intimate with men; that she is now carrying a child by some man; that she is annoyed by a certain woman kicking her bedstead during the night; that she is accused of going out nights with men; that certain persons attempt to poison her. Talked constantly, protesting her innocence; was in constant motion with her head and hands; cried and swore. Appearance and manner that of an excited, nervous, irresponsible person. Has grown thin and haggard during the past three months, and her delusions are more fixed. She left the dinner-table and went out to vomit poison that had been concealed in her food; wrings her hands; cries and talks of her imagined troubles while at her work."

Physical examination on admission revealed the cardiac impulse in the nipple line, feeble first sounds,

[1] The Goulstonian Lectures on Insanity in Relation to Cardiac and Aortic Disease and Phthisis, the British Medical Journal, March, 1888.

greatest intensity of second sounds in third costal interspace, and irregularity of beat. During her residence in the hospital patient has been subject to paroxysms of excitement characterized by activity, during which she walks anxiously up and down the ward, wringing her hands, weeping, and complaining that she is being poisoned and otherwise injured, and apparently entirely overcome by her fears. On February 14, 1894, physical examination revealed displacement of the apex-beat to the nipple line, and a blowing systolic murmur entirely replacing the first sound of the heart, with maximum intensity at the apex and



Tracings showing the Effect of Digitalis upon the Pulse, with Coincident Improvement in Mental Condition.

area of convection from a point midway between the pulmonary interspace and the apex to the ensiform cartilage, and laterally as far as the anterior axillary fold. With the use of a prescription containing tincture of digitalis, tincture of the chloride of iron, and whiskey, the patient was rendered more comfortable and there was less severity of the mental manifestations, with more frequent remissions. With discontinuance there was marked change in the character of the pulse, and more pronounced mental agitation and excitement.

The Genito-urinary System.—That there should be great divergence of opinion upon the relations of kidney and mental disease follows naturally upon hospital neglect of systematic urinalysis, and indifference to mental manifestations on the part of the practitioner. Dr. Osler's[1] recent work is almost alone in assigning to insanity a prominent place among the cerebral symptoms of uræmia. That somnolence, stupor, vertigo, headache, spasm, convulsions, coma, and delirium might and do arise from the same causes as mania and melancholia is not inconsistent with our knowledge of the relations and functions of the brain. I recall four conspicuous cases of uræmic insanity, of which two resulted in death, one in chronic insanity, and one in restoration to mental health.

Case No. 1688.—Man, admitted to the hospital May 18, 1894, aged sixty-five, widowed, nativity United States, fisherman, temperate. Assigned causes of insanity, rheumatism and nephritis. At the time of admission patient was feeble and pulse was 96, feeble, and of high tension; temperature, 99.2°; tongue dry and with brown coating; pupils contracted; and urine contained albumin, uric acid, and hyaline and granular casts. The heart was hypertrophied and the beat forcible and labored. This was his first attack of insanity, and was said to have existed for one month. Patient's attending physician stated: "He has had rheumatism for twenty-five years: the last attack was in July last, and he was confined to his bed for four or five months. When I first saw him, about May 1st, he lay in a comatose condition which continued for four days. He now takes milk, voids his urine involuntarily, and also his bowels. He will be in constant motion for hours at a time, then again there will be a sort of cataleptoid condition. Will hold a cup or a pillow in a certain position for hours at a time. Sometimes it requires two or three persons to restrain him and keep him in bed." The medical certificate of insanity stated: "Said nothing intelligible. Lies in bed most of the time, picking at the bed-clothes or pillow; at times gets out of bed and tries to go out of doors. He is thus busily engaged for hours at a time, and then will fall asleep from exhaustion. Emaciated; eyes sunken and have a vacant stare. The brother states that for several weeks before this attack his actions were peculiar, and at times he would appear more or less dazed and talked incoherently."

The patient was given a liberal amount of liquid diet and the bowels were kept open by the use of frequent doses of Epsom salt. Diuretic and tonic drugs were ordered. He improved steadily, and on August 7, 1894, three weeks after admission, he was discharged from the hospital mentally recovered, taking with him a caution upon the dangers of his Bright's disease and the possibilities of recurrence of his uræmic state.

The Respiratory System.—The revolution of opinion as to the communicability of tuberculosis is not without marked effect upon present understanding of the relations between insanity and this fatal complication, which holds so prominent a place in the mortality tables of hospitals for the insane.[1]

That the debilities of insanity furnish suitable opportunity for the propagation of the tubercle bacillus is consistent with the theories of its life history; that something more is required is strongly suggested by the experience at the St. Lawrence Hospital. Beside the subsidence and cure of tuberculosis in a few instances present upon admission to the hospital, the mortality rate has been surprisingly low. Since the opening of the institution in December, 1890, to the present time (September 1, 1894), there have been 228 deaths. Of these the cause of death in 19 cases was assigned directly to tuberculosis, and in 17 additional

[1] The Principles and Practice of Medicine, p. 738.

[1] In the New York State hospitals during the fiscal year 1892, of a total of 682 deaths, 79 were attributed to phthisis pulmonalis, 4 to general tuberculosis, and 20 to pulmonary tuberculosis; while of other causes, exhaustion from the various forms of mental disease stands first, with 126 cases, followed by general paralysis of the insane with 68 cases. Report of the New York State Commission in Lunacy for 1892, pp. 272 et seq.

cases, in which death was due to other causes, and in which autopsies were made, tubercular lesions, for the greater part latent and subordinate, were discovered. During the fiscal year ending September 30, 1893, there were 75 deaths, of which 6 were due to some form of tuberculosis. Of 14 deaths occurring at the Clinton State Prison at Dannemora, N. Y., during the same period, 10 were due to tuberculosis. With almost entire exemption from other causes in the latter institution, there had been no decrease in the mortality from tuberculosis.[1]

The climatic conditions of the two institutions are not dissimilar. Both lie upon the border of one of the great health-resorts for consumptives of America. The hospital is new, and in its construction hygienic and sanitary principles had careful and perhaps elaborate consideration. It receives inmates from whom absence of physical debility of one form or another is the exception. At Dannemora no insane people are retained.

In the light of these facts the question of the relation of insanity and tuberculosis resolves itself into a consideration of the predisposition of the two diseases. In seeking their cause we are attracted by the theory of the functions of the nervous system advanced by Dr. Maudsley:[2] "Perhaps I might set it down as a true generalization that the morbid neurosis, when it is active and gets distinct morbid expression, may manifest itself in four ways: *a*, in disorder of sensation—for example, paroxysmal neuralgia; *b*, in disorder of motion—for example, epilepsy; *c*, in disorder of thought, feeling, and will—mental derangement; *d*, in disorder of nutrition—whereof diabetes is the earlier and phthisis is the later stage." And in Dr. Blandford's[3] classic treatise on insanity is written: "I have found, however, that phthisis and insanity do frequently co-exist in the same family, but that some members will be afflicted with insanity, while others suffer from phthisis, and that this is the rule rather than that both disorders co-exist in greater or less degree in all the members of the family."

To this Dr. Stearns[4] adds the weight of his experience: "We often see that a consumptive patient has a child, which instead of developing consumption develops insanity, and *vice versa*, an insane person may have children of a phthisical tendency."

Case No. 1151.—A girl, sixteen years of age, was admitted to the hospital September 25, 1893. She was said to have been insane eight years, and her attacks had been of an epileptiform nature, characterized by sudden outbreaks of violence, and probably associated with unconsciousness, either partial or complete. Heredity was the assigned cause; eight paternal great-uncles and great-aunts had died of phthisis, and her paternal grandfather was epileptic in youth, and neurotic. During her residence in the hospital—which was for little more than six months—she had an attack of intractable bronchitis and laryngitis with marked laryngeal congestion and aphonia, and also a subacute inflammation of the sheath of one of the flexor tendons of the palm of the hand.

To Dr. Clouston's[1] analysis of the mental symptoms of phthisical insanity, little has been added: "Looked at solely from the point of view of the mental symptoms present, some of the cases would be called mania of the mildly delusional, slightly demented type; more of them would be called melancholia, also of the mildly delusional type; and many of them would be called monomania of suspicion. It is a very striking fact, in regard to the last, that nearly all pure cases of monomania of suspicion sooner or later die of phthisis."

Case No. 1189.—A young woman, nineteen years of age, was admitted to the hospital November 12, 1893. She was feeble and exhausted, and was easily confused when attempting to answer questions or to discuss her condition. Physical examination revealed consolidation of the right apex, a cavity in the left apex, and an open sinus from the sternum. The cause of her disease was said to be tuberculosis. Patient remained fairly quiet until about three weeks after admission, when she became restless, apprehensive, and suspicious. She wept a great deal, argued and disputed about trifles, and was incoherent, and at times unintelligible, in conversation. She removed the dressings from her wound. Her respirations were accelerated, and at times there was increase in temperature. She complained about her treatment, and resisted the care of her nurses, speaking indefinitely of her fear that she was being injured, that her trinkets and clothing were stolen from her, and she manifested the greatest degree of apprehension. A month later she became more quiet and settled, but she spent the greater part of her time in bed. Her excitement subsided and there were no indications of cough or further active process in the lungs. This improvement has continued, and at the present time she is cheerful and rational, entirely recovered from her mental disease, and is steadily gaining in weight.

Constitutional Diseases.—In his discussion of diabetic insanity, Dr. Clouston[2] naïvely remarks: "The psychology of most bodily diseases is yet to be written. One has a faint hope that the clinical study of mental diseases by students of medicine may so familiarize their minds with mental symptoms, that they will be more on the alert to look for them in their ordinary practice than they would otherwise have been. When they are looked for by those who know how to observe and name them, they will be found. The whole history of medicine is one long tale of finding things when they are looked for."

Case No. 1007.—The patient, a married woman, aged fifty-six, a native of Canada, was admitted to the hospital May 11, 1893. No history accompanied her. The medical certificate stated that she had been violent, dangerous, destructive, and excited, and homicidal during paroxysms; she had said that her neighbors were all her enemies, that she was continually the object of their persecution, and that she had lost all her property; that people surrounded her house at night, peering into her windows, and otherwise annoying her. Physical examination revealed fair strength. No marked

[1] Dr. J. B. Ransom: Tuberculosis in Prisons, read at the Congress of National Prison Associations, held at St. Paul, June, 1894: "A year prior to my taking charge of the medical department of Clinton Prison, the mortality rate of the institution was upon the daily average 3 $^{41}/_{100}$ per cent. from all causes, while for the year closing September 30, 1893, it was $^{87}/_{100}$ per cent., showing a marked decrease. At the same time there was an increased mortality from tubercular disease, and, in spite of all efforts that have been put forth and which have proved so efficient in lowering the death-rate from all other diseases, have completely failed to proportionally lessen the advance of tubercular disease. The mortality from this disease was numerically small, but as a percentage large. . . . An examination of prison mortality statistics of this State, computed upon my estimate, would show that the percentage of deaths from tubercular disease prior to 1880 was less than forty per cent., while since that time it has steadily increased until 1890, when it reached a percentage of over eighty."

objective symptoms. Glycosuria was determined, and the patient was placed upon anti-diabetic diet. She improved rapidly under this course of treatment, and in four months the sugar disappeared from the urine and she was discharged from the hospital, recovered from her insanity.

Case No. 590.—The patient, a married woman, aged thirty-three, a native of Canada, was first admitted to the hospital March 7, 1892, and was said to have been insane for ten weeks, the attack having followed epidemic influenza. She was debilitated and melancholy, but improved rapidly under tonic treatment, and upon May 30th appeared entirely rational and bright, and was discharged from the hospital.

Upon July 11, 1892, she was readmitted to the hospital. Her husband stated that she became excited at the time of her previous discharge from the hospital, while on her way to the train, and that she had been threatening and violent during her residence at home. She expressed indefinite ideas of persecution, saying that her neighbors came into her house and seized knives, and she acknowledged that she had been frightened by them and incited to commit acts of violence. As her husband turned to leave the building, a circumscribed area of baldness was seen under his thick hair, and upon the suggestion afforded by this the wife was placed upon treatment of potassic iodide and bichloride of mercury. She improved steadily, gained rapidly in weight, and in the following February was discharged recovered. She has since remained at home.

Imperfect and fragmentary as are these records, they point with unerring directness to the common basis of mental and physical disease, admitting for the brain no exception from the general laws of the organism, and recognizing no fundamental distinction between its mental and its motor, sensory, and trophic functions. Receiving peripheral impressions, it organizes, adjusts, and reflects them, toning and completing the clinical picture. Is there one among us so bold as to claim that he alone has mastered its tints, its lights, and its shadows?

Garbage Disposal in Birmingham.—In his work on "Municipal Government in Great Britain," Mr. Shaw thus describes the means employed for the disposal of garbage in Birmingham: Each house is also supplied with a specially designed ash-tub for kitchen garbage and other solid refuse as well as ashes; and the contents of these are emptied into a box attached to the van that removes the "pans." The whole work is organized by districts with perfect system. There are several receiving-stations, all located on canal wharves. The coarser garbage is consumed in furnaces, of which there are about fifty in operation. The fine contents of the ash-pits are mixed with a portion of the contents of the closet-pans, forming a fertilizer that is removed by canal-boats and sold to farmers. But most of the material from the pans is made into a dry, powdered fertilizer by evaporation in special machines. The heat derived from the burning garbage suffices to work the evaporating machines. The "poudrette" fertilizer is sold at $30 a ton. The residuum of the incinerated garbage is a mass of "clinkers," useful for concrete or mortar, for road-making, or for filling low ground. The Health Department makes large use of the canals that radiate from Birmingham, and owns thirty or forty capacious canal-boats, which are in constant use for the removal of fertilizers and other final products of the sanitary works which deal with the cleansings and refuse of a great city. All in all, Birmingham has evolved a most complete and satisfactory system for the public management of every form of waste material—a system adapted in all its parts to the actual conditions of the place.

The Hospice Salpetrière, made famous by the names of Pinel, Esquirol, Trélat, Vulpian, and Charcot, was first established in a building that had been originally a factory of saltpetre, whence its name. The buildings were first converted into an arsenal, and then in 1653 set aside as a home for aged and indigent women. In 1684 a prison for the detention of prostitutes was built in the centre of the grounds. A century later this building was turned into an asylum for the incurably insane. In 1862, when Charcot first became attached to the institution as chef de service, the population of the Salpêtrière was about five thousand.

An Annual Census of the city's population is much needed, according to the City Health Department, and the Mayor has been asked to arrange that one be made.

DYSENTERY.[1]

By W. C. WEBER, A.B., M.D.,
CLEVELAND, O.

Dysentery, one of the great epidemic diseases of the earth, is said to have killed more men in armies than have powder and shot, and is more fatal in the tropics than cholera. This, a disease of the large intestine, assumes a number of forms, but is essentially an inflammation of the membrane, and is characterized by frequent stools, tormina, and tenesmus in the early stage.

While most prevalent in hot countries, sporadic cases occur in all climes, and under favorable conditions the disease may become epidemic. But wherever the newer sanitary ideas have been put into practice and the teaching of bacteriology observed, there dysentery has diminished in all its forms. This statement is strengthened by the experience of many hospitals; let it suffice to refer to Montreal General Hospital, in which 150 cases were treated during the ten years ending in 1879; in the succeeding decade there were but 31. In the United States it has been epidemic a number of times, notably during the Civil War.

The acute catarrhal form in this climate is most prevalent in the summer and autumnal seasons, and while the exact mode of its production is not thoroughly known, it is probable that decomposition of animal and perhaps vegetable matter plays an important part. Not that the process of decomposition is so much the causative agent as the micro-organisms developed by this process. Sudden changes in temperature seem to wield a greater influence in bringing on an attack of dysentery than do moisture and alleged impure water.

Dyspepsia and constipation are conditions which predispose to the disease, stress being laid especially on the latter. It is a well-established fact that in all regions where malaria abounds the disease under discussion is most common, and it is very probable that the conditions which give rise to malarial fever are similar to those concerned in dysentery.

Pathological Changes.—The lesions are situated in the large intestine and occasionally in the ileum. The mucous membrane is swollen and injected, and sometimes is covered with blood-stained mucus. An important feature is the enlargement of the solitary follicles; these project conspicuously from the membranes, and in the more prolonged cases the follicles suppurate or are capped with necrotic tissue. When these break down, the colon is studded with ulcerations. In children the disease sometimes takes the form of an acute follicular colitis. Sometimes the inter-follicular spaces also become necrosed, and then the whole mucous membrane presents vast areas of ulceration.

Essentially the pathological changes in the chronic form of the disease are the same as those described; usually the submucous and muscular coats are thickened, thereby decreasing the lumen of the intestine, but seldom producing stricture. Ulcers in this form are generally present and cystic degeneration of the glandular structure may occur. Pulmonary and renal complications are also said to be frequent.

The amœbic form of the disease is distinguished chiefly in that the amœbæ coli are constantly present in the evacuations, and that abscesses of the liver are frequently concomitants or rather sequelæ of the affection. In other respects this variety does not differ pathologically from those before mentioned; and inasmuch as this type is a disease indigenous to the tropics, we will dismiss it with this mere reference and turn our attention for a few moments to the diphtheritic variety. This is much more severe than the simple inflammatory form; it is characterized by an exudation of fibrin, pus-cells, and blood on and through the mucous membrane, which in time sloughs, and results in loss of tissue; when this destruction involves the greater portion of the large intestine, death is inevitable; or when the deep structures are included in the morbid process, peritonitis and agglutination of the intestinal coils may take place. It should be noted that diphtheritic dysentery is in no way related to diphtheria of the throat; it receives its name on account of certain resemblances to the pharyngeal disease.

The diagnosis of acute dysentery, as a rule, presents no difficulty; the premonitory symptoms are griping abdominal pains, frequent alvine evacuations, and tenesmus. The stools soon become covered with mucus or a muco-purulent secretion, and not infrequently are streaked with blood. Fever and thirst and sometimes headache may be symptoms. This rapid drainage soon renders the patient very weak, when, coincident with the discharges, profuse sweating may occur, and even syncope has been known to follow within a few hours of the initial attack. The evacuations in a short time lose their feculent character, and then almost entirely consist of mucus, epithelial *débris*, and blood.

The chronic form differs from the acute more in intensity in the latter, perhaps, than in any other respect. It may be mistaken for various chronic diarrhœas; this error can usually be avoided by eliciting the history, which in the great majority of cases reveals the fact that the chronic was preceded by an acute attack. Fever is absent; periods of intermission and at times constipation alternate with the diarrhœa.

Anæmia and emaciation are sequelæ, unvarying in their presence in the later stages of the disease. Acute dysentery is occasionally mistaken for acute enteritis, intussusception, or typhoid fever. The stools in typhoid are not as frequent, but generally larger, thin, and "like pea-soup." The characteristic temperature curve of typhoid, the rose-spots, and epistaxis are absent in flux. In enteritis the stools are less frequent, more copious, and the tormina and tenesmus wanting. The attack of intussusception is more sudden, the pain is more constant and fixed, vomiting is the rule, and the bowel may protrude. Intussusception occurs most often in children, dysentery in adults. This seems to me to be the picture, very briefly outlined, of dysentery in its general sense, and its connection with or relation to the diseases which have been already mentioned. Let us for a few minutes consider its treatment.

Treatment.—The treatment of dysentery has undergone great changes in recent years, and it varies to-day according to the view entertained as to the pathological character of the disease. In the acute affection the object to be accomplished, doubtless, is the removal, as far as possible, of irritation and the placing of the part at rest; this seems rational, and does no violence to the particular theory one may hold in reference to etiology or the pathological alterations which occur. To carry out the former, evacuants are indicated; the drastics should be avoided; any of the mild cathartics which act promptly and effectively may be used; the saline salts in very large doses perform good service. Calomel is a favored remedy with a considerable proportion of the profession; it seems especially popular with the French, who teach that as soon as the stools contain bile they regard the case cured. It is prescribed both in large and small doses, preferably the latter, frequently repeated.

Another therapeutic agent also exhibited for its chologogue effect, and with which I have but a very limited experience in this connection, is ipecacuanha. It is administered in full and often-repeated doses, carried almost to the point of nausea; this is said by many close observers to be excellent treatment.

Having now succeeded by some of the means suggested in evacuating the intestinal tract, the next indication—that of rest—is to be observed. For this purpose opium has been the *sine qua non* for a considerable time and still holds its place with many. There is little doubt that it exerts a desirable influence in controlling pain, modifying peristalsis, etc., thus contributing much to the comfort and cure of a certain number

[1] Part of a discussion before the Cuyahoga County Medical Society, October, 1894.

of cases. But when we consider the gastric and secretory disturbances produced by opium, and when we observe that the local condition is not only not ameliorated but aggravated in consequence of the retention of the secretions and other intestinal products, it becomes questionable whether this drug should be used at all in this disease. When, for special reasons, it seems indispensable, the alkaloid should be used in the hypodermic form.

Personally, I avoid the employment of opiates whenever possible, except in cases of severe pain and tenesmus, and then only in the form suggested. Topical treatment, in the form of variously medicated enemas, are in vogue in certain quarters with varying success. Usually an astringent, such as silver nitrate, zinc sulphate, copper, etc., in weak or strong solution, according to the fancy of the adviser, is prescribed ; as a rule these are not well tolerated in the acute stage.

In the acute stage the plan of treatment which I pursue is the following : Evacuate the intestinal tract promptly by means of a mild cathartic—the salines, but more preferably the mild chloride of mercury, in minute and frequently repeated doses. This done, bismuth subnitrate, gr. xx., and salol, gr. iv., are administered combined from every two to six hours, the astringent and antiseptic action of this prescription having a pleasant sedative effect on the colon. When pain is intense and the tenesmus severe, $\frac{1}{4}$ gr. of morphia hypodermically is of much value in conjunction with the bismuth and salol. The patient should be in bed, the diet albuminous liquid, so that as small a residue as possible remains.

In the event that the treatment just sketched should fail in its purpose, which occasionally it does, as all plans of treatment do at times, I resort to lavement of the large intestine. The condition or indication which suggests the use of the irrigation is the severe straining and great discomfort in the rectal region which persist in some instances in spite of any or all internal medication. The lavement consists simply of large injections of cold water, to be retained a few minutes, and repeated when the symptoms demand it. Many times after the first flushing the former severity of symptoms does not return, when, nevertheless, it is advisable to repeat the irrigations at intervals of three to four hours. I have just stated that cold water should be employed. This point is to be emphasized ; the water from the hydrant is not always sufficiently cold for this purpose. The best results that I have ever achieved came from the effect of ice-cold water. This treatment is not as disagreeable or severe as it may appear to some ; the beneficial effects are immediate and pronounced.

The treatment of the chronic form cannot be thoroughly discussed here, the length of this paper having already extended beyond its intended limit. I will, however, mention a few of the salient points bearing on this subject. As a general statement it can be said that the proper regulation of the diet constitutes the most important part of the management. The mineral astringents, before alluded to, applied topically, are probably of more value in the chronic than in the acute stage ; of these, a strong solution of $AgNO_3$—20 to 30 grains to the pint—in large quantity is the best preparation, as originally recommended by Dr. Hare. Hot water, at 100° F., is vaunted by some as a curative measure.

In Johns Hopkins Hospital they speak in laudatory terms of warm injections containing quinia 1 to 5,000, or 1 to 2,500, especially for the amœbic variety of the disease. The constitutional treatment in the amœbic and debilitated patient is by no means of secondary importance, and should receive appropriate medication.

This brief and imperfect consideration of dysentery may serve in a measure as a general guide, and may, we hope, lead to a more thorough discussion of the subject by the members of this Society.

OSTEOPLASTY FOR RELIEF OF SYMPTOMS CONSEQUENT UPON HERNIA OF THE BRAIN RESULTING FROM FRACTURE OF THE SKULL WITH LOSS OF BONE.

By AUGUSTUS C. BURNAYS, M.D., M.R.C.S., Eng.,

PROFESSOR OF ANATOMY AND CLINICAL SURGERY AT THE MARION SIMS COLLEGE OF MEDICINE, ST. LOUIS.

Reported by HOWARD CARTER, M.D.,

FIRST ASSISTANT ; LATE SENIOR ASSISTANT AT THE ST. LOUIS CITY HOSPITAL.

The following case was operated upon at a clinic given at the Rebekah Hospital of the Marion Sims School of Medicine at St. Louis, Mo., as a compliment to the members of the Mississippi Valley Medical Association.

The patient, Edwin A——, aged twenty-one, white, male, occupation jockey, was thrown from his horse while riding a race on July 27, 1893. When on the ground he received a kick upon the head from another horse, producing a depressed fracture of the frontal bone. Both tables were punched in and the dura mater considerably lacerated, and hemorrhage from the dura was not severe, and no clots were found, nor was any loss of the cerebral cortex apparent. The depressed portion was almost circular and a little larger than a silver dollar. For facility in describing its location I will suppose it to be circular and inscribed within a square whose posterior edge is formed by a portion of the coronal suture, its anterior by a parallel line two inches above the margin of the supra-orbital ridge, its inner edge formed by a line parallel to and three-fourths of an inch to the left of the sagittal suture, and its outer by a line parallel thereto one and one-half inches above the temporal ridge. The broken fragments were removed and the rough edges of bone trimmed, and the external wound packed with iodoform gauze by the attending surgeon.

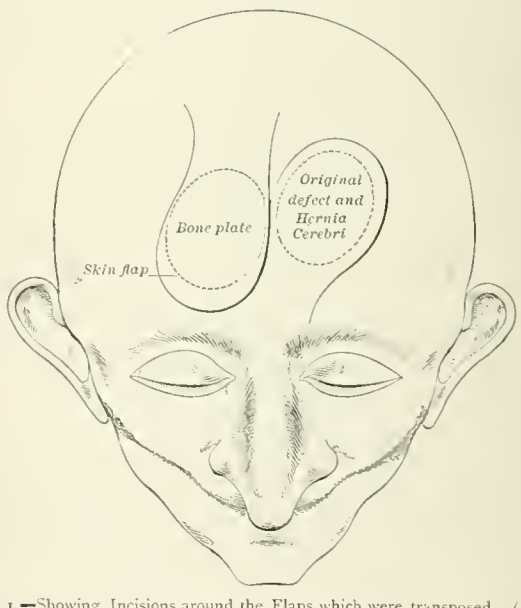

Fig. 1.—Showing Incisions around the Flaps which were transposed. (About three-fourths of natural size.)

The patient was completely stunned by the force of the concussion and remained for sixteen days in an unconscious condition.

After the return of consciousness recovery was rapid, some suppuration occurred, and the wound closed by granulation. Patient experienced a sensation of fluctuation in the region of the injury, but otherwise appeared to be in normal health. Nine weeks after the accident he was able to resume his customary occupation, which he followed without experiencing any inconvenience and with his usual success, until eight months after the first receipt of injury. He had ridden a race, and while returning his horse to the stable he suddenly felt a sensation of dizziness and almost immediately lost consciousness. He was in this condition for about ten minutes, and appears to have been dazed and confused

for the remainder of the day, but was sufficiently recovered to resume work the following day.

During a period of eight months, ten similar seizures occurred with progressive intensity; the longest interval between any two attacks was eight weeks; the greatest frequency, two in one day; the next greatest frequency, three in one week. These attacks were invariably preceded by and associated with emotional excitement and presented many characteristics of true epilepsy. Convulsive movements were bi-lateral, very severe, and confined to the upper extremities, and were accompanied with frothing and biting of the tongue. A sensation of dryness in the fauces was the only premonitory symptom, and this invariably ushered in an attack. No closer approach to an epileptic aura appears to have been present, and the return of consciousness was sudden and complete.

The liability to and frequent recurrence of these attacks incapacitated him from pursuance of his occupation, and he was forbidden to ride by the judges of the race-track.

Upon examination, the site of the injury was found to be densely cicatricial; the cerebrum could be distinctly felt and seen pulsating through the smooth scar-like skin. The portion of cerebral cortex in contact with the cicatrix was located anterior to the fissure of Rolando; the symptoms could not be referred to constant pressure. The hyperæmia caused by excitement and violent exercise unquestionably produced increased protrusion of the cerebral hernia, and the symptoms could be referred to pressure of the cortex against the bony edges of the opening through which it occurred. An operation was decided upon for the radical reduction of the hernia by transplantation of a skin-bone flap, after a modified König's method.

Operation.—The head was shaved and made aseptic by the application of a 1 to 1,000 bichloride pack, which was kept in place during the night preceding the operation. A double semilunar incision was made in the scalp, the left semilune enclosing the site of the injury and all the cicatrical tissue in connection with it, the right semilune included that portion of the frontal and right parietal bone bordering upon the sagittal and coronal sutures.

The diameter of each semilune was about two and one-fourth inches, and they were cut, one with anterior, the other with posterior convexity. (See Figure 1.) The cicatrical covering of the cerebral hernia was elevated and its edges stripped from the circumference of the opening. The scalp covering that portion of the frontal bone which was selected for transplantation was not detached from the bone, the edges only being slightly retracted to permit the free use of the chisel. A portion of suitable size was marked off and the outer table cut through with a sharp chisel, great care being required to prevent the detachment of the pericranium and scalp. A thin chisel was then inserted between the outer and inner table and gradually worked around the circumference of the gutter previously cut, gentle hammering being kept up so as to drive the chisel between outer and inner table. Owing to the large size of the graft the chisel could not be passed entirely through the diploë to the other side. The force exercised in separating the tables produced a stellate fissuring of the outer table. A small artery of the diploë was ruptured and its course clearly traced for about one-half inch. This was stripped of the attached osseous material and then ligated. Hemorrhage was at no time sufficient to interfere with or delay the operation. The detached portion, consisting of the outer table, pericranium, and scalp, was then swung round upon its pedicle and approximated to the opening in the skull, the edges of which having been first freshened with the scalpel. Considerable difficulty was experienced in handling the graft in preventing the separation of pericranium and bone graft. The cicatricial tissue and scalp which had originally covered this area were next slid over the recently denuded outer surface of the inner table, the edges being trimmed into perfect apposition. A line of continuous sutures was inserted around the edges of the entire wound, a dressing of aseptic gauze applied, and the scalp immobilized with a plaster-of-Paris skull-cap.

The patient rallied from the operation in one hour and made an entirely afebrile recovery. The edges healed by the first intention, and the transplanted bones are united to the new bed made for them over the defect. Convalescence has been somewhat delayed by the sloughing of a small transplantation of skin smaller than a silver quarter of a dollar on the forehead; otherwise the wounds have healed without suppuration and no infection has followed the sloughing. Three weeks after the operation patient attended a dance and suffered no inconvenience in consequence.

Eight weeks after the operation the granulated portion of the wound had fully cicatrized, and there is every evidence of progressive though as yet incomplete osseous union. I have good reason to anticipate a very gratifying result. The operation of osteoplastic closure of skull defects by this method is one which will undoubtedly gain a permanent place in surgery and should be practised in all suitable cases of hernia cerebri. In this case the defect is now covered by bone, and the surface shows no depression or elevation, but is perfectly normal.

Union Trust Building, St. Louis, Mo., January 15, 1895.

REMARKS ON ECTOPIC GESTATION.[1]

By FRANCIS FOERSTER, M.D.,

PROFESSOR OF DISEASES OF WOMEN TO THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; GYNECOLOGIST TO THE GERMAN HOSPITAL AND DISPENSARY; CONSULTING GYNECOLOGIST TO THE LUTHERAN HOSPITAL, BROOKLYN.

The subject of ectopic gestation is of intrinsic interest to the general practitioner as well as to the gynecologist; it renders to both the opportunity to show diagnostic ability, and enables the surgeon to demonstrate his good judgment and operative skill, sometimes under the most embarrassing circumstances. Undoubtedly during the last few years general practitioners have made considerable progress in the recognition of the characteristic symptoms, admitting thus of an early surgical interference. This advance in the diagnostic faculty has to be valued so much higher as we know that there is no sharply defined line of symptoms which can be laid down as pathognomonic of this disorder. On the contrary, this knowledge can only be attained by an attentive study of the literature on the subject, by comparing a series of cases, abstracting therefrom the most striking features.

It has become the general opinion that the life of the patient rests mainly in the hands of the family physician, inasmuch as on his early recognition of the prevailing symptoms depends in a great measure the ultimate result of the operation. As a further progress we have to note that for some time past the expectant plan of treatment has been given up almost altogether. The injections of strychnia, of ergot into the fœtal sac have become historical; the morphia injections are practised by a few of their earlier advocates. To-day we hear only occasionally of a case where electricity has been resorted to as an agent to destroy the life of the fœtus; the immediate as well as the remote danger connected with these measures have become fully appreciated by the profession.

We shall not go wrong in stating that among progressive practitioners the conviction prevails that the only way to do full justice to our patients in cases of ectopic gestation is in advising and carrying out of an early operation.

[1] Read before the Metropolitan Medical Society, New York, December 18, 1894.

Experience has shown that even cases which are apparently beyond all hope, where the excessive intraperitoneal hemorrhage has been exhaustive, are by no means so hopeless that an operative interference could not bring about a favorable issue. Proportionately to the increasing interest in the subject, we find the medical literature overburdened with the reports of cases. An ailment formerly considered of rare occurrence has become so common that every practitioner meets with such cases, every gynecologist has been called upon to operate more or less frequently. But the zeal of reporting these has been carried too far in a good many instances. It has become a general idea that all collections of blood found in the tube, or between the folds of the broad ligament, or even in the free abdominal cavity must be looked upon as the result of an extrauterine gestation. While this is true in a good many instances, there are conditions where such a statement does not hold good.

I could enumerate from my own experience a number of cases where I found as the source of hemorrhage pathological conditions in the ovary, hæmatomata, which were fully sufficient to account for the hæmatosalpinx in the closely adherent tube, an hæmatocele in the abdominal cavity, or an hæmatoma in the folds of the broad ligament. Besides, cases are on record in which sarcoma of the tube-walls caused considerable hemorrhage. We cannot, therefore, declare ourselves satisfied with an off-hand assertion of ectopic gestation in these cases; for accurate diagnosis we have to resort to microscopical examination of the contents of the wall of the tube, or the débris otherwise found in the abdominal cavity. The presence of chorionic villi or of decidual structure must be established in first line, provided that we are unable to find the fœtus.

Four years ago I reported five cases of ectopic gestation which came under my observation in private practice in the comparatively short period of about two years. In narrating these cases I ventilated the views current at the time, giving my own opinion and adding suggestions which came to me in scrutinizing these cases. Since that time I had the opportunity of operating in a fair number of cases. I will not fall back on these, but will base my remarks on five cases which occurred to me during my last service at the German Hospital, and two cases which I observed at the German Dispensary.

These last two cases I consider as specially valuable, and I will, therefore, without giving the history in full, speak on the pertinent points of interest.

The first patient came to me with the usual history. Menstruation, which was formerly regular, had been delayed several days and was very scanty in amount. She had suffered from colicky pains in the left ovarian region for several days; the pain diminished in severity gradually. On examination I found close to the uterus a mass which extended downward and backward into Douglas's pouch, the surface somewhat uneven, the consistency doughy, on pressure moderately sensitive. There was a slight chocolate-colored flow from the vagina. As this patient had been under treatment before and nothing in shape of a tumor was detected in the left parametrium, and as the breasts secreted colostrum, I only could look upon the case as one of ectopic gestation, probably tubal abortion. I did not consider this an instance of rupture of the tube, as the hemorrhage had either apparently come to a stop, or was progressing so slowly as to allow the effused blood to coagulate around the thrown-out products of gestation in Douglas's pouch. In tubal rupture we rarely hear of such a cessation occurring; smaller or larger arteries are spurting from the torn surfaces and do not come to rest until a large amount of blood has escaped into the abdominal cavity, the blood-pressure then being considerably diminished.

In tubal abortion the ovum escapes through the abdominal end of the tube, and a slow venous bleeding from the secundines in the tube is the result. Since the patient was not willing to submit to an operation and this was not imperative, and the state of health being besides a fair one, I decided to wait for further developments, recommending rest in bed. The patient has reported weekly, the tumor has decreased in size, so that to-day only a small, irregular nodular mass can be felt in Douglas's pouch.

The lesson to be learned from this case is apparently to follow the expectant plan whenever we find that the patient is not in imminent danger. Yet I would consider such a conclusion fallacious.

Although the stage of acute anæmia has been safely passed at the time, it can happen that a renewed hemorrhage may set in, putting the life of the patient in immediate jeopardy. The products of gestation, thrown from the tube into the abdominal cavity, are liable to implant themselves in the most undesirable localities.

An illustration of such an occurrence I will give in the course of this paper. The fœtal development after rupture of the sac or after abortion from the tube may proceed, exposing the patient to the dangers of an extensive operation later on, or it may come to cessation, forming in the woman's abdomen an inert mass, the destiny of which is uncertain. Under the most favorable circumstances the peritoneum will absorb the effused blood and even the ovum, the latter especially, when advanced in development, often being converted into a lithopædion. This process is naturally a slow one. The patient meanwhile, being continuously under the apprehension of an unfavorable issue, suffers both mentally and physically. But granted that absorption did take place, we still have the residue of the sac in form of a hard cicatricial mass left *in situ*. We still have to deal with the diseased tube, originally the starting-point of the trouble. Such a tube we cannot expect to return to the normal state; on the contrary, it will constitute a permanent menace to the welfare of our patient; the slightest provocation will suffice to cause it to become once more the centre of irritation. The safety of the woman is not assured as long as this degenerated organ remains in her body.

The expectant plan, therefore, cannot be considered seriously any longer. The treatment of ectopic gestation under all circumstances consists in operative interference, *i.e.*, ablation of the hopelessly diseased parts and removal of the products of gestation from the abdominal cavity. When the anamnesis and the physical examination point to the probability of ectopic gestation, I claim the operation should be performed even to the risk of being based on an erroneous diagnosis. The diseased state of the tube and likely the ovary always found in these cases warrants the laparotomy.

As to the mortality, the surgical cases compare most favorably with those treated in an expectant way; the earlier the operation is performed the less dangerous it is; it ought to be almost absolutely safe in the hands of experts. Even in neglected cases, where septic symptoms are developing, we should not desist in our efforts; we may gain by our bold interference what would otherwise be absolutely lost, namely, the life of the patient.

The second case, a woman, aged twenty-four, has gone through several early abortions; no children.

She noticed that the last menstruation was rather scanty and somewhat delayed. For two weeks she complained of constant pain in the left ovarian region. On examination I found close to the somewhat enlarged uterus a mass of the size of a walnut, apparently in the first third of the Fallopian tube. The breasts upon pressure secreted colostrum. She was under observation a full month; has been demonstrated repeatedly in my clinics as a case of ectopic gestation. Seven weeks after the last menstruation she noticed a slight bloody, watery discharge from the vagina, considerable pelvic

pain, followed by a profuse hemorrhage, which kept her in bed for several days.

When presenting herself she was still flowing. On examination I found that the enlargement, which had grown to the size of a crab-apple, had disappeared, the cervical canal was patulous, indicating that the woman had recently aborted. Undoubtedly this was a case of tubal gestation in the segment nearest to the horn of the uterus. Nature, assisted probably by the repeated examinations, has taken care of the case.

If an electro-therapeutist would have obtained control of this case, he surely could have claimed the favorable outcome as a result of his efforts. I believe galvanism can assist nature most effectively in such early cases of tubal gestation, where the products are located in the uterine portion of the tube, or the portion next to the uterus, as long as the distention of the tube has not gone so far as to force apart or to completely destroy the muscle fibres and deprive them of their power of contraction. In the first few weeks we notice even a thickening of the muscular coat, analogous to the increase of muscular element of the uterus. Galvanism then can be used with a certain degree of safety; massage may likewise be beneficial; but the moment the distention becomes excessive, galvanism as well as massage become risky procedures. This case took a most favorable termination, it is the first one in my experience where I was enabled to watch nature's efforts to my full satisfaction. Many cases are reported of a similar character, and although we must consider such an outcome feasible, I was sceptical about it, looking upon the diagnosis of such cases as an erroneous one; they may have been pregnancies, I thought, in the horn of the uterus or in the interstitial portion of the tube.

The five patients I operated upon in the hospital were, with the exception of one, the routine cases. I will not tire you with their histories, but will simply state that four were cases of tubal abortion and one of ruptured tubal gestation. All of them recovered. Where the fœtus was not found the microscopical examination of the tube cleared all doubt as to the nature of the morbid condition. It is only within the last few years that tubal abortion is recognized to be by far the most frequent outcome of tubal gestation. I regard it of so frequent an occurrence that many cases may escape observation.

In conclusion I would like to give the history and account of the operation in a case of tubal abortion that, owing to its complications, I deem of special interest.

S. G——, aged thirty-eight, married fourteen years, two children, youngest aged four; no abortions. Menses regular up to four months ago, when she passed eight days over her usual time. The bloody, watery flow was accompanied by intense pain in the right side of the abdomen, so that she had to stay in bed ten weeks. The pain did not diminish in severity for four weeks. She had a short period of rest followed by a profuse metrorrhagia, which reduced considerably the otherwise robust woman. The pain in the right side gradually became lessened, but her exhausted condition and the continuous flow forced the patient to enter the hospital.

The examination per vaginam revealed two distinct masses, the one of the size of two fists at the right side of the uterus, very sensitive on pressure, of irregular outlines and doughy consistency; a second, semi-fluctuating tumor at the left side of the uterus and closely adherent to it, filling Douglas's pouch. The uterus pushed to the right side measured four inches. Temperature 102.2° F.; pulse 110, of bad quality; constipation. My diagnosis was: extra-uterine pregnancy complicated by cystomyoma uteri.

On opening the abdomen I found a considerable quantity of old coagulated blood on the omentum and between the loops of intestines. At the right side of the uterus I found a large, greenish tumor imbedded between the intestines, bordered above by the transverse colon, to the right by the cæcum. The vermiform appendix entered this mass at the extreme right. An effort to free the same from its adhesions resulted in a tearing of the appendix both from the cæcum and the mass itself. An opening of the sac was thus caused large enough to allow a quantity of the semifluid contents to escape into the abdominal cavity. The brownish-green fluid was extremely offensive, consisting of blood decomposed by the admixture of fæcal matter. The general abdominal cavity was fairly well guarded by gauze pads, but not sufficiently to keep this unexpected flow of fetid material within bounds. Some of the liquid escaped upward, soiling the intestines and anterior surface of the liver.

Under the circumstances I could do nothing better than to free the rotten mass as quickly as possible from its adhesions with the intestine. The sac contained besides the fluid a decomposed fœtus and placenta of the third month. The remaining stump of the appendix was ligated closely to the cæcum. The considerably hypertrophied tube showed no rupture, the abdominal end being patulous. The odor from this foul liquid was so intense that we were compelled to bathe our hands in a strong solution of hypermanganate of potassium, using the same solution on pads, to wipe out the abdominal cavity. I applied a temporary tampon to stop the extensive bleeding from the denuded peritoneal surfaces. I proceeded then to remove the tumor on the left side. After considerable difficulty I was able to enucleate unruptured a large pyosalpinx containing 4 to 5 ounces of pus. I inserted gauze drains in different directions and closed the abdomen in the usual fashion. The result was a most satisfactory one. Highest temperature after operation 101.4° F.; the pulse was frequent and of poor quality for a few days, but improved under stimulation. The patient left the hospital in the usual time. I am not amiss in considering this case of interest enough to devote a few minutes to a closer analysis. I would first point to the difficulty in the diagnosis. From the statement of the patient and the prevailing symptoms, it was comparatively easy to diagnose an ectopic gestation. There was no point, however, in the history which would be explanatory of the presence of the huge pyosalpinx. This accumulation of pus could not have been of recent date, the adhesions binding the salpinx down closely to the side of the uterus were quite firm, so that I may state that the patient has carried this pus-bag for years without being materially influenced by it. I would next call your attention to the peculiar part the vermiform appendix played in this case. It is the common experience of every gynecologist to find in tubo-ovarian disease the appendix frequently bound down by pseudo-membrane in close proximity to the diseased parts. Often is the appendix itself so much pathologically changed that we are unable to say whether the ovarian disease was primary or whether secondary to the appendicitis. Although I have seen cases where the ovarian disease only could be caused by the well-marked pathological condition of the appendix, where in a cystic ovary only one cyst, being closest to the appendix, contained pus, nevertheless I would say that generally the opposite holds good, namely, the appendix is secondarily involved. In woman a peritoneal fold unites the appendix to the ligament of the ovary, which explains the easy transmission of inflammation from one organ to the other.

In this case the pregnant right tube aborted its contents into the abdominal cavity unluckily in such a way that the appendix became involved near the placental site. The consequence was a gradual erosion of its coats and an ultimate rupture, allowing the fæcal contents of the intestines a free communication with the sac, resulting in speedy death of the fœtus and decomposition of the contents of the sac.

It is further interesting to note how kindly the peritoneum took all the insults offered during the operation. We frequently see that in operations for pyosalpinx or ovarian abscess the diseased portion cannot be removed without rupture of the abscess and the escape of more or less pus into the abdominal cavity; rarely we do see ill effects to follow; the peritoneum seems to have acquired a certain tolerance for this infectious material from having been for some time in close contact with it. In this case we may assume that immunization has taken place to a certain extent, or else it would be difficult to explain that such material as fæcal matter and decomposed blood should have been borne by the peritoneum without producing the slightest reaction.

39 West Fifty-second Street.

Progress of Medical Science.

Lethal and Non-lethal Effects of Strong Electrical Currents.—Dr. Bernhardt has collected several instances of death by electricity. In one a man aged twenty-six was traversed by a current of high tension—one thousand six hundred to two thousand volts—and was found breathing stertorously a few steps from the point where he made contact. Death soon took place. The post-mortem examination, after the lapse of twenty-one hours from the time of death, disclosed two small wounds—one on the left index-finger and the other on the back—and there were large extravasations of blood in their vicinity. All the organs of the body showed hypervenous blood, acute œdema of the lungs was present, and there were extravasations into the sheath common to the carotid and vagus, along all the vertebræ, into the intercostal spaces, around the œsophagus, beneath the peritoneum, and elsewhere. The muscles of the body were in an extreme condition of rigor mortis; the heart was partially relaxed. No macroscopic changes could be seen in any part of the nervous system. Kratter thinks that the electrical shock suddenly paralyzed the heart, which was the immediate cause of death, accompanied by œdema of the lungs causing hypervenosity of the blood. There was a marked contusion on the left side of the diaphragm at the point of contact of the heart. Experiments made on animals showed that in them the respiration was usually primarily arrested, which caused asphyxia and secondary stoppage of the heart's action, though sometimes the heart was first affected. In a second case, reported by M. D'Arsonval, a man was struck with a current of four thousand five hundred volts. The current entered at his hand and issued at his back. Half an hour or more elapsed before any attempts at resuscitation were made, but on artificial respiration being practised on Silvester's method, recovery took place. Dr. Donnellan reports a case of the passage of a current of one thousand volts through a man, which instantly caused coma, dilated pupils, pallor of the face, and sweating; delirium and tonic, alternating with clonic, spasms followed. The pulse was 80. The respiration, at first stertorous, passed into the Cheyne-Stokes type. After the injection, first of morphia, and then of strychnia, the patient fell into a deep sleep, from which he awoke convalescent.—*Centralblatt für die medicinischen Wissenschaften.*

Indicanuria.—Dr. Gehlig gives the following conclusions, based upon a considerable number of observations upon children both sick and well:

1. Nurslings in good health or children fed upon sterilized milk, and not the subjects of digestive troubles, sometimes present a trace of indican in the urine.

2. If digestive disturbances occur almost always some indican is found, its quantity varying with the gravity of the affection. In chronic catarrh of the intestine, cholera, and typhoid fever, it is particularly marked.

3. In older children without digestive trouble, the urine normally contains indican. If the diet includes a high proportion of nitrogenous food (eggs, meat), indican becomes more abundant.

4. There exists no relation between tuberculosis and a more or less marked indicanuria.

Cima has published the results of examinations in 68 cases. Most of these children were fed simply on bread and milk, some on bouillon, vegetables, and eggs, and others on mother's or cow's milk.

1. Cases of clinically declared tuberculosis of abdominal or thoracic organs—10 cases. Almost all had some irregularity of digestion, and the stools were mostly liquid or semi-fluid. In 99 analyses, 69, or 69.69 per cent., gave positive reactions, while medium or very marked reactions were given in nearly half, or 45.5 per cent. In these same cases very marked reactions were obtained after some days of feeding upon a diet richer in albuminoids, or during constipation. On the other hand, the reaction was slight or feeble when the children were put upon milk or had liquid or semi-fluid stools.

2. Cases suspected of tuberculosis, with adenopathy, chronic catarrh of intestines, or intermittent catarrh of bronchi—23 cases. In 73 analyses, 75.34 per cent. gave positive reactions, or 46.57 per cent. of medium or marked reactions.

3. Cases of divers acute and chronic diseases—35 cases. In 88 examinations, 38 were without reaction, while 30 per cent. of medium or marked reaction were given for the most part by children over two years of age nourished on a mixed diet.

The conclusion from these results is that the indican reaction in the urine is more positively connected with anomalies of digestion, especially in mixed feeding, than with the principal malady. Consequently indican has no other diagnostic importance than that of indicating the degree of decomposition of albuminoid substances in the intestines.—*American Journal of the Medical Sciences.*

Tumors of the Placenta.—Dr. Edward Alin observed an interesting case of this nature in a III-para, twenty-nine years of age, the placenta weighing twenty-one ounces. In the marginal portion there was a solid tumor as large as a hen's egg, and another the size of a walnut, in the centre of the placenta. (*University Medical Magazine.*) Both tumors were made up of numerous smaller ones, varying in size from the head of a pin to a hazel-nut. The tumors could be easily distinguished from the rest of the placental tissue by their compact appearance. There were no other tumors, infarcts, or hemorrhage, or any condition which would indicate an impediment in circulation, and no inflammatory areas or signs of degeneration. The tumors were found to consist of capillary vessels, surrounded by scanty connective tissue with few cells. There was no trace of a sarcomatous structure. The endothelium of the vessels consisted of a single layer, with well-defined cells, coloring easily. The author regarded the tumors as due to hypertrophy of the chorionic villi with abundant vascularization.

A Tombstone in Burlington, Ia., has this stanza:

> Beneath this stone our baby lays,
> He neither cries nor hollers;
> He lived just one and twenty days
> And cost us forty dollars.

Photographing the Womb.—A Swiss physician has described a method of dilating the uterus by means of tents, so that by the use of a mirror a perfect view may be obtained of the interior of the organ. Not content with this, however, he is unselfish enough to desire to obtain photographs of the uterine interior in various diseases of the organ. The future of woman is sad indeed, if now her womb must not only be felt of, sounded and measured, but photographed as well.—*New York Polyclinic.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, March 30, 1895.

AN ABSURD CHARGE AGAINST A NAVAL SURGEON.

THE friction between the staff and the line of the navy is again quite prominently brought forward in the forced attempt to define more directly the amenities and official relations which should exist between the two arms of the service. It seemingly involves the question whether Fleet Surgeon Kershner neglected his duty as a medical officer of the United States Navy by declining to attend to a case of sickness on board a Nova Scotia vessel at Barbadoes. The reflection cast upon Dr. Kershner by Admiral Meade, aside from the report in the matter of the Nova Scotia vessel, is characterized as gratuitous, and, in view of the fact that Dr. Kershner was reported to have been active in working in opposition to the Personnel bill, which failed to pass Congress, it is interpreted as a movement on the part of the line to "get square" with him.

The vessel in question was but a short distance from the flag-ship New York, and also near shore, when the call for medical assistance was made. The medical inspector declined to respond to the call, fearing that there might be cases of yellow fever on board the strange vessel, and that the crew of the war-vessel might become thereby infected. Again, the said ship was near shore, where an abundance of good medical service could be obtained. Although it was proved subsequently that the case was a simple one, the captain of the flag-ship very ingeniously made charges against the surgeon, on the plausible plea of want of humanity on his part, and struck a keynote which has reverberated along the upward line of condemnatory endorsement, until the papers are now in the hands of the Secretary of the Navy.

Surgeon Kershner very properly answers to the absurd charge by maintaining that one of his first and most important duties is the protection of the health and lives of the men and officers of the fleet; also, that his advice to send to shore was, under the circumstances, perfectly reasonable and eminently proper.

The charge of inhumanity is a grave one in any event, but to a medical man it is particularly disgraceful in view of the fact that the medical profession, above all others, glories in its self-sacrificing devotion to the helpless and suffering. From a sentimental side the captain poses as the high-priest of Samaritanism, and makes the best of the text in hand to read a telling lesson to the poor culprit of a medical officer.

In point of fact, however, the surgeon did his full duty in the premises. His duty as an officer of the navy is to attend to navy business. His functions as medical officer are entirely confined to the ship and the crew. His whole time and strength belong to them when he is on duty. There is nothing in the letter or spirit of naval discipline or duty that militates against this principle. The case in point was not strictly one of humanity, but of mere convenience on the part of the Nova Scotia crew, as the shore was as handy as the war-vessel. If the two ships were on the high seas and one needed help of any kind, there would be no room for any doubt as to what should be done. Plain duty would supersede even so-called questions of humanity.

It is somewhat difficult for civilians to understand the grounds upon which any charges can be made by one officer against another under the circumstances. In fact, it would appear that the captain and admiral have gone out of their way to make out a case on side issues only. It was certainly not a violation of duty by the naval surgeon not to respond to an outside call, and such being the case, the line officer has no jurisdiction in the premises to call the medical officer to account, much less to trump up the absurd charge of inhumanity to outsiders, while the medical officer was doing his best to care for and protect those of his own crew; and worse than all, to endeavor to create a public sentiment against such an officer by covertly subjecting him to the prejudiced, discourteous, unmanly, and irrelevant endorsements of his superiors of the line.

CARDIOCENTESIS AND CARDIAC SURGERY.

DR. ALLEN THOMSON SLOAN relates, in the *Edinburgh Medical and Surgical Journal*, the history of a remarkable case of cardiocentesis, and gives a history of cardiac aspiration and cardiac injuries which suggests that the heart may yet come within the domain of modern surgery.

Dr. Sloan's patient was a young woman who had had acute rheumatism following erysipelas. Endocarditis and pericarditis set in, the patient suffered great pain, and grew progressively weaker. At 8 P.M., June 13th, she had a syncopal attack and was apparently moribund; ether was injected with no effect. Aspiration of the pericardium had been suggested and the aspirator made ready, but its use was postponed because all the physicians considered the case hopeless. Finally the heart and respiration suddenly stopped. In a moment of excitement, Dr. Sloan thrust the aspirator needle into the chest in the fourth intercostal space, half an inch to the left of the sternum. To his dismay he found that pure blood immediately rushed into the aspirator, to the amount of eight or ten ounces, and then stopped. As the doctor slowly began to withdraw the needle, he noticed that the heart began to beat: more ether and one-third grain of morphia were injected, and breathing returned; and after several hours of distress and weakness the patient began to show evidences of having passed the critical stage. In fact she steadily regained strength, the rheumatism ceased entirely and at once, and in a few months the patient was practically well.

She recovered from her acute rheumatism as well as

her endo- and pericarditis, directly, as it appeared, from the aspiration of blood from the heart.

Dr. Sloan goes over the history of heart punctures and heart injuries, but finds only one case that measurably resembles his own.

In 1872, Roger, while performing pericardicentesis on a child with pericardial effusion, thrust the needle into the right ventricle and withdrew six and one-fourth ounces of pure venous blood. The boy, who was aged five, became pale, sweated, and had an imperceptible pulse.

The withdrawal of the pericardial fluid, accomplished prior to the heart injury, was beneficial; and the cardiac puncture did no permanent mischief, for the patient recovered. Death occurred five months later from long-existing dilatation and valvular disease of the heart.

Other cases in which heart puncture and aspiration were resorted to are reported by Westbrook, Dana, Colwin, Evans, Bouchut, and Fischer. In some instances temporary relief was afforded, in all no harm was done, but in none was there such a brilliant and permanent success as Dr. Sloan records. The late Dr. B. A. Watson, of Jersey City, made some experiments upon animals from which he concluded that: 1. Puncture of the heart, especially of the right ventricle, stimulates muscular contractions, and may be advantageously employed in the treatment of chloroform narcosis. 2. The best results are obtained when abstraction of blood from the cavity of the ventricle is combined with the stimulating effects produced by the entrance of the aspirator needle. 3. Puncture of the right ventricle is a safe and more efficient operative procedure than puncture of the right auricle. His reasons for this last conclusion are two. In the first place, the wall of the right auricle is much thinner, and contains less muscular tissue than the wall of the right ventricle. The auricle is in every respect a sort of reservoir for the blood. The propelling power, to a great extent, belongs to the strong muscular walls of the ventricle. There is another reason why we should not puncture the right auricle, namely, as the wall of the auricle is thin, there is more danger of blood escaping. In no case of puncture of the right ventricle was there any leakage from the interior of the cavity.

Dr. Sloan collects a great many cases of injuries of the heart, showing how tolerant this organ often is of cuts, stabs, etc.

In the "Index Catalogue of the Army Medical Museum" there are reported twenty-two cases of direct injury to the heart, all of which lived over three hours; seventeen lived over three days; eight lived over ten days; two lived over twenty-five days; one died on the fifty-fifth day; and there were three well-authenticated recoveries. Dr. S. S. Purple, of New York, gives in the *New York Medical Journal* (vol. xiv., p. 441) an account of a recovery from a wound penetrating both ventricles (confirmation of the diagnosis by post-mortem nine years subsequently), and a tabulated list of forty-two cases which survived injury for from thirty minutes to seventy days. Dr. C. E. Lavender, in the "Proceedings of the Medical Association of Alabama" (1851, pp. 104–181), reports a recovery from an incised wound of the heart; and Dr. C. L. Ford, in the Medical Record (1875, p. 173), cites a case of buckshot injury, with recovery.

In view of all the facts the writer finally puts the question: If cardiac tapping can be done successfully by accident, are there any cases where it should be tried as a deliberate remedy? And the answer, he thinks, must be in the affirmative. In all cases of asphyxia, where the heart's action has stopped, cardiocentesis followed by artificial respiration seems the proper treatment. Thus, in cases of suffocation by drowning, accidental hanging, by carbonic acid, carbonic oxide, coal, or sulphuretted hydrogen gases, in cases even of still-birth, some good effect might follow the introduction of the needle. It is not always possible to have an aspirator ready for such emergencies: but desperate cases require desperate remedies, and a small trocar and cannula, or the hypodermic syringe, might, if used at the proper moment, have a totally unlooked-for beneficial effect. In cases of chloroform asphyxia it is worth trying, and in some cases of heart affection, of pneumonia, and even of bronchitis, where all other means have failed, and where the patient is evidently dying of engorgement of the right side of the heart, a possible chance of saving life might be lost were cardiac aspiration not attempted.

THE SALE OF PATENT MEDICINES.

The editor of a New York daily paper stated not long since, on the authority of a manufacturer of patent medicines, that there had never been a time when the sale of these nostrums had been greater than during the past year. The editor thought the matter one worthy of consideration by physicians, though he offered no suggestions as to the course they ought to pursue to draw the public away from this cult of the kidney controller and peristaltic accelerator. Indeed, he would not be likely to do so, for the advertisements of these quacks pay the newspaper well.

The chief reason for this increased sale of patent medicines is no doubt the hard times. The people feel poor, and they think it more economical to prescribe for themselves, which they all regard themselves as perfectly competent to do, and thereby save the doctor's fee. And besides, they know these remedies are good, for they are all certified to by prominent lawyers, artists, literary men, clergymen, and of late even physicians. We have nothing to say in the way of protest against the clergymen's certificates. The writing of them seems to be regarded by many clergymen as part of their regular clerical duties, and their influence is probably no greater than that of the ordinary sermon. Literary men, too, who are often very like clergymen in their apparent ignorance of the ways of this sinful world, should not be too sternly chided for their childlike faith in the efficacy of their favorite prescription, especially as the pay for such work, compared with syndicate rates, is enormous. But the lawyer and the artist cannot be excused on the plea of innocence. When district attorneys and clever caricaturists sit down and write endorsements of the efficacy of injurious stimulants, the presumption is that they know what they are doing and why they are doing it. We do not

now recall the name of any reputable physician who has ever certified to the efficacy of any avowedly patent medicine, and we are fain to believe that there is none such; but more than one with whose names, for one reason or other, the public has become familiar, have repeatedly lent their names to help the sale of some proprietary medicine or food preparation, advertised, with certificate attached, in the daily papers as well as in the medical press. The public still has some respect for medical opinion, though not always willing to pay for it, and the certificate of one physician of prominence has more weight than one signed by the whole house of bishops or by the full bench of police justices. It is not so much to be wondered at, therefore, that all this stuff is bought and presumably swallowed by a confiding public.

But despite these pan-professional endorsements, there is little fear that this evil will continue. It is only one of the indications of the hard times, and as soon as general business revives the people will again indulge in the luxury of medical advice for minor ailments, and then the quotations for certificates from prominent lawyers, clever illustrators, and well-known physicians will fall again to approximately their true value—which is naught.

"WHEELS."

One of the curious ways in which persons of unstable mind have been popularly characterized is to say that they have "wheels in their head." The derivation of this vernacular we cannot undertake to explain. Perhaps it is because persons of nervous and excitable temperament often suffer from tinnitus aurium or sensations of buzzing in the head. The patient often feels as though he had buzz-saws or much strident and unlubricated machinery in his head. A Western alienist has been greatly taken with the wheel theory of the anatomy of crankiness, and has drawn for a daily paper the picture of the wheel in the head of an alleged insane wife-murderer. The hub is a delusion of persecution, and the spokes are his litigious, erotic, hypnotic, scientific, and other manifestations, of which the periphery is made up of systematized ideas. The picture does not speak much for the alienist's psychological knowledge, and its publication evidences still less of good taste. But it illustrates the popularity of the wheel idea of insanity. We venture to say that many people will, in a certain degree, acquire a belief that there are material things revolving in the brains of the unbalanced, and in the name of science and sense we protest against the use and popularization of psychological slang on the part of those who are supposed to be men of scientific knowledge and training.

The Craig Epileptic Colony.—The utterly unreasonable and disreputable attempt to legislate Dr. Frederick Peterson and his associates from the management of the colony ought not to be tolerated in the Legislature. Dr. Peterson is virtually the creator of this beneficent institution, and to deprive it of his guidance now would be a deplorable step.—*New York Medical Journal.*

News of the Week.

Preliminary Examination for Medical Degree.—Senator Smelzer's bill, providing that the degree of "M.D." shall not be conferred in this State unless the candidate shall have had a preliminary examination, representing, in 1898, one year's academic work, in 1899 two years' academic work, and in 1900 a full high-school course, has passed the Senate.

Hot Springs.—Within the next year Hot Springs will likely have the finest sanitarium in the country. The Knights of Pythias, five hundred thousand in number, are to be taxed $1.00 per capita, the Grand Lodge of Arkansas has donated $5,000, the city of Hot Springs has given the site, and doubtless many other contributions will be received.—*Hot Springs Medical Journal.* Hot Springs seems in need of a small-pox hospital just now.

Beriberi in Ireland.—The outbreak of a disease so oriental in nature and name as Beriberi in an Irish lunatic asylum is a very remarkable circumstance, yet it appears to be a veritable fact. The disease seems to have made its appearance early in September, and to have rapidly reached a climax in about a month. There were one hundred and ten cases under treatment in the first week of October. It has subsided with equal rapidity, and the latest accounts indicate that, with the advent of winter, new cases have ceased to appear, though some one hundred and fifty seizures, with twenty-three deaths, have taken place. The diagnosis seems to be beyond question, both the dropsical and paralytic symptoms which constitute the principal feature of the malady being well marked.

Patent Communion Service.—A Michigan clergyman thinks he has solved the individual cup problem. The Rev. Charles E. Lee, of the Second Baptist Church, Grand Rapids, Mich., has invented an individual church communion service and has had it patented. It consists of a pyramid of three disks attached to a central standard. The disks have apertures into which seventy-five tiny cups shaped like grapes repose, each holding a spoonful of wine. At the top of the standard is a ring and swivel. A long handle with a hook at the end is used in passing the standard. The hook fits in the ring at the top, and by turning the disks around the filled cups are always easily reached. As rapidly as used the cups are inverted, and there is an attachment to catch drippings. The disks and standard are made of any metal desired, and are susceptible of elaborate ornamentation. The grape cups may be of silver, gold, or china, according as a church may desire.

The Berlin Anglo-American Medical Society, at its meeting on March 1st, elected the following officers: Ferdinand C. Valentine, M.D., of New York, *President*; Earle Straine, M.D., of Fall City, Montana, *Vice-President*; and H. R. Wossidlo, M.D., of Potsdamerstrasse 117, Berlin, *Secretary* and *Treasurer*. Among the objects of the Society are the presentation of papers, interesting cases, etc., and their discussion at meetings held every two weeks; assisting those who come to Berlin for special studies in promptly obtaining

all the information and advice they need for the furtherance of their purposes, and thus saving them much trouble and valuable time. The requirements for membership are: presentation to the secretary (who must be a permanent resident of Berlin) of the applicant's passport and diploma or his matriculation card in the Berlin University. The dues are: Initiation fee, 4 marks; annual dues, 4 marks while in Berlin, and 2 marks annually thereafter.

An Epidemic of Rabies has appeared among a herd of cattle in Mankato, Minn.

Influenza in St. Petersburg.—It was estimated that there were about fifty thousand cases of grip at St. Petersburg on March 1st.

An Unsuccessful Attempt was made recently to expel a Brooklyn physician from the King's County Medical Society because, as was alleged, he published an article in a daily paper.

A Coroner's Jury on the Perils of Foot-ball.—An inquest was held at Hexham, England, recently on the body of a player, who died on March 5th from injuries received in a foot-ball match, played under Rugby Union rules, on the previous Saturday. On a verdict being returned in accordance with the medical evidence, which showed that the unfortunate man had died from the effects of a collision between his head and the hip of an opponent whom he was attempting to "collar," the jury added a recommendation that a revision of the Rugby Union rules to make the game less dangerous was necessary. With this sentiment we, says *The Lancet*, are in accord, but we should like to see the suggested revision of the rules of either code; we should like to read some serious proposals for lessening the perils of the game which had emanated from players thoroughly familiar with all the details of both codes.

Dr. G. W. Bratenahl died at his home in this city, on March 18th, aged twenty-eight.

The Medical Practice Act of Tennessee.—The Medical Practice Act of Tennessee has been declared unconstitutional. The *Southern Practitioner* says it has no tears to shed over this decision, and thinks the best thing to be done is for the Legislature to repeal the whole thing and get it out of the way.

The Passing of the "American Lancet."—With the issue of the *American Lancet* for the current month, Dr. Leartus Connor, after a service of nearly twenty-four years, retires from the editorial chair, and with his withdrawal the publication of the *Lancet* comes to an end.

Mt. Sinai Hospital.—By the provisions of the will of the late Dr. Gronhut, Mt. Sinai hospital will receive about $50,000.

A Town in the Drug Business.—Under the heading "Is this Town Going into the Drug Business?" the *Sun* recently published a letter, signed "Medicus," which with the omission of an irrelevant paragraph read as follows: "I learn from to-day's paper that the Legislature may authorize the New York Health Board to manufacture and sell 'antitoxin,' and that the Mayor has been urged by officials of the board to indorse the measure. . . . Since when is it necessary for a health board to manufacture therapeutic agents and to sell them in competition with legitimately established business concerns? And if it is right and proper that the anti-diphtheritic serum be thus manufactured and sold on a business basis by our health board, why may not the scope of this department be enlarged, and the manufacture of other medicines be engaged in? Why not also bake bread, slaughter cattle, make butter, etc.? The people certainly are in need of such supplies too, and if medicines, why not food? Good and 'health board guaranteed and made' food will prevent sickness, as 'health board serum' and other drugs will cure. Your report says that 'Commissioner Edson and Secretary Clark of the department, appeared in favor of the bill and no one in opposition.' I feel sure that if due notice of the hearing had been published, medical men and those interested in the manufacture and sale of the serum would have been there to say that the board's competition as a purveyor of the serum is not necessary, and that reliable firms are supplying all that is needed now, and at reasonable prices. Give the opponents a chance to be heard. But, above all, don't let a communistic measure, establishing a city department in business as competitor of citizens, pass and go into effect."

Dear "Medicus," the town is already in the drug business, and has been for years, so we fear your protest comes too late; nevertheless it is gratifying to find that at last one New York physician appreciates the situation, and your letter shows a distinct advance from the attitude which, ten or twelve years ago, the local profession presented when the Board of Health was empowered to engage in the production and sale of vaccine, to the inevitable detriment of certain physicians who, by their own exertions, had overcome a tremendous prejudice against animal vaccination, certainly without any moral support from the board, if not against the additional impediment of secret discouragement from individual officials serving under the board. Not only was there then no protest from the physicians of New York, but physicians even lobbied in favor of the bill, to their discredit be it said.—*New York Medical Journal.*

Quarantine Examination by Electric Light.—Our new Health Officer, Dr. Doty, has arranged to use electric light when necessary in the examination of passengers on incoming steamers. In this way it will be possible for vessels to pass Quarantine after sundown. The new arrangement will add greatly to the comfort of travellers.

The Medico-Chirurgical Faculty of Maryland proposes to secure a home for itself in Baltimore, and a committee appointed for the purpose has selected a ten-thousand-dollar house.

Private Hospital for Contagious Diseases.—In addition to the $25,000 subscribed originally for this hospital by Mrs. Minturn, nearly $25,000 more have been subscribed.

A Hospital's Doctors Resign.—The medical and surgical staff of the Alexian Brothers' Hospital, of Elizabeth, N. J., have sent in their resignations to the rector of that institution.

Society Reports.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, January 4, 1895.

HENRY F. WALKER, M.D., PRESIDENT, IN THE CHAIR.

The Treatment of the Diffuse Form of Septic Peritonitis as a Result of Appendicitis; with Cases.—DR. CHARLES MCBURNEY read the paper (see p. 385).

DR. ROBERT ABBE thought the author had adopted the best method of getting at the truth with regard to grave cases of appendicitis—that is, by giving them serious study and relating both good and bad results. He agreed with him, that the technique of the operation was coming to be better appreciated, and when carried out on the lines indicated he thought it would be possible to save a good proportion of these worst cases. The report of cases of appendicitis as they ran by the hundred, was not of great value in the present study, because so many of them were simply cases of abscess or pus which had become locked in. But where there was distinctly diffuse peritonitis the condition became so grave as to demand immediate and vigorous action in order to prevent fatal termination. Indeed, it seemed to him one of the greatest triumphs of surgery that any of them at all were saved. The report in the paper of 27 cases with 13 or 14 recoveries, gave a most wonderful result, one with which an operator could well be satisfied. Yet he had no doubt but what in time, by observing the advance which had already been made, even this percentage of recoveries would be improved upon.

On looking over the record of cases which he had seen at his office the past five years, not having had the time to examine the records of those seen at the hospital, it appeared that the number operated upon was 67, with 8 deaths. Seven of the entire number were found to belong to the class discussed in the paper, and of these 7, all of which were operated upon, 3 recovered. There was the same diffuse peritonitis, with no tumor to be felt as in confined cases, and most of them having a history of from a few hours to a day and a half. One of them was seen as late as the seventh day, that of a doctor's child with grave general suppurative peritonitis, but it was not likely the peritonitis had been general all this time. In fact, it seemed to him that many cases of general suppurative peritonitis were not so at the first, although there was a class which might fairly be called diffuse general suppurative peritonitis from the start. In the other class the inflammation was locked in, feebly confined, but after two or three days rupture took place and general peritonitis followed. These, he thought, could properly be classed among the grave cases which could to-day be saved by operation. They presented the same symptoms which the author had described, absence of tumor or even of dulness in many instances, the pus being smeared over the caput coli and small intestine, or escaping as a soapy fluid with the first incision through the abdominal walls. In two of the three cases which recovered gauze drainage was employed; in the other there was combined with it the use of a drainage-tube in the loin. Dr. Abbe still thought the tube had advantages, but it was not necessary in the majority of cases, and probably almost always should be dispensed with. He believed the gauze tamponade, introduced lightly into all pockets, succeeded best in sucking the peritoneal cavity dry and in purifying it.

In drawing out the wicks, introduced in all directions, one point had struck him as of considerable importance. Owing to their adhesion to the intestine within twenty-four or forty-eight hours, one was apt to pull unduly upon the gut and to cause the patient pain. But by twisting the gauze into the shape of a rope as it was withdrawn, it became detached, fibre by fibre, and caused much less disturbance.

Dr. Abbe thought that if bad cases were studied carefully, it would be found the result depended very much upon their care the first twenty-four hours after the operation. In his judgment the first important thing was to revive the patient from shock; then sustain him until the restorative powers could act and give the system a chance to suppress the septic infection.

One thing not mentioned by the author was valued very highly by the speaker, namely, rectal injection of hot coffee and whiskey, half an ounce to an ounce of whiskey to a teacupful of hot black coffee immediately after the operation. For washing out the peritoneal cavity he regarded salt solution as undoubtedly the best.

DR. CLEMENT CLEVELAND inquired whether Dr. McBurney and other surgeons had made use of peroxide of hydrogen in peritonitis. He had not employed it himself, but he had heard some gynecologists speak favorably of it. He had not operated for appendicitis himself, nor did he expect to, but it had occurred to him that it might be advantageous in such cases, as in certain gynecological operations, to drain through the posterior cul-de-sac into the vagina. In other operations he had never regretted having resorted to that form of drainage.

DR. W. M. POLK thought the author had struck the keynote of the situation when he resorted to gauze drainage. The fact that one could displace large bodies of intestine without doing the patient any great harm taught a lesson which should not be lost sight of in connection with this work. In women with peritonitis following labor or abortion, of which cases he saw not a few at Bellevue, the ideal procedure would be to get rid of the uterus as the surgeons got rid of the appendix in appendicitis, but unfortunately, hysterectomy under such circumstances was attended by too great shock. In view of this fact, they had found their best results were obtained when they disregarded the location of the intestine and had isolated the uterus as far as possible, by the kind of gauze-packing mentioned by Dr. McBurney, then leaving the abdomen widely open. Of course, the interior of the uterus received treatment. In abortion at the third month, for instance, the uterus was small and the intestines sank into the pelvic cavity. On opening the abdomen they were lifted up and an abundance of gauze was packed about the uterus, completely isolating it. He thought it was very important to bring all the region, the seat of the infection, under the capillary drain, however extensive it might be.

Regarding salt solution, he had been very much impressed with its efficacy, but he was not sure that it did not cause adhesions. One of his assistants had had occasion to reopen the abdomen of a patient operated upon six months or a year before, at which time there were no adhesions and the salt solution was employed. At the second operation the adhesions were as abundant as he had ever seen. He had therefore been interested to hear Dr. McBurney's statement that the salt solution caused no adhesions when used in joints, and the supposition was that there would be no risk of its doing so within the abdomen.

DR. KINNICUTT remarked upon the great pain caused by removing gauze from the abdomen, and said that if it could be avoided by any method whatever it would prove a great boon to patients.

DR. POLK had found the removal of gauze least painful when it had been introduced by the Mickulitz method.

The President, DR. WALKER, remembered that some years ago, when Dr. Thomas used the glass drainage-tube with side perforations about the size of a small knitting-needle, hernia of the intestine took place into these minute openings in one case, after which Dr. Thomas abandoned the side perforations.

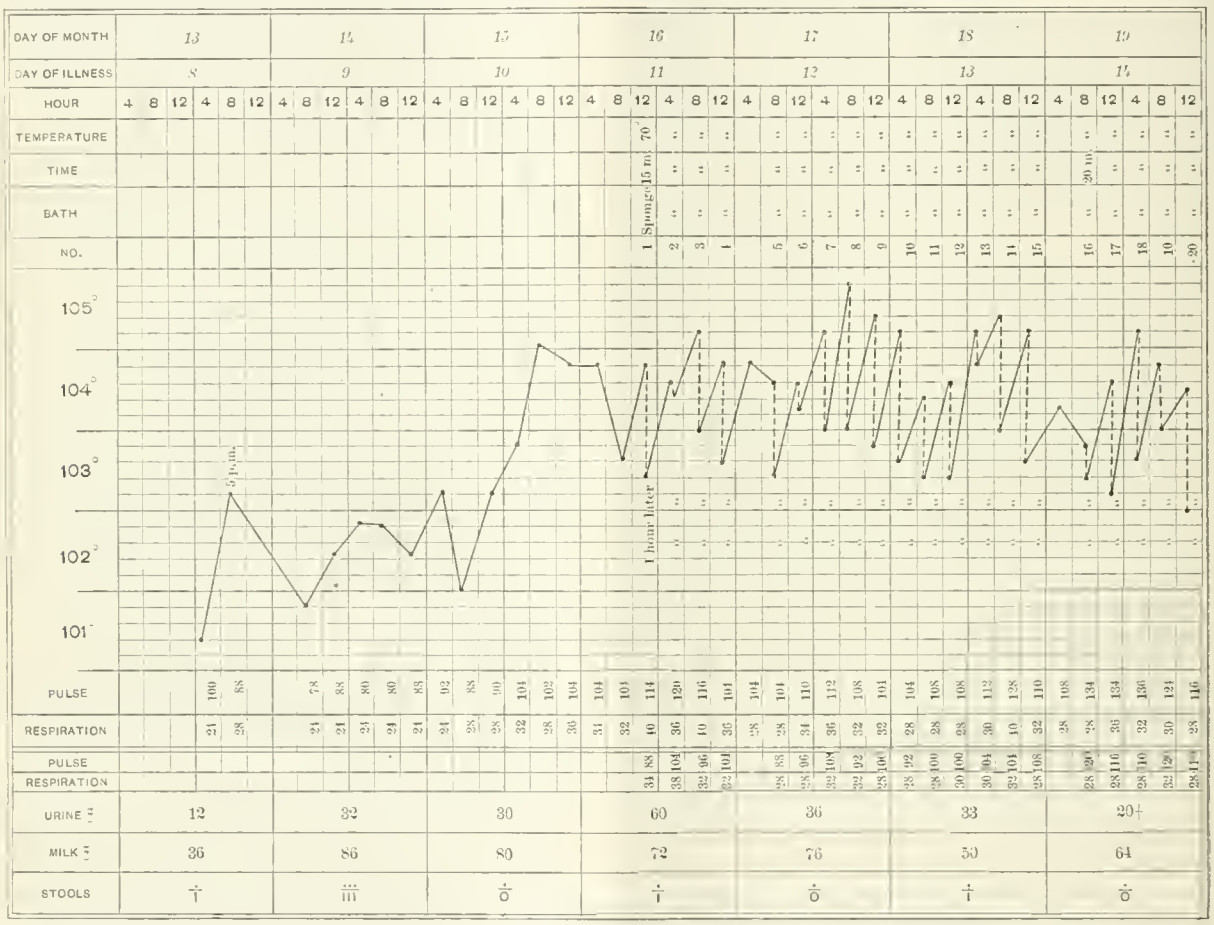
Dr. Polk inquired of Dr. Cleveland what was the salt solution used at the Woman's Hospital a number of years ago, its strength, whether sterilized, and why it was abandoned.

Dr. Cleveland replied that it was his impression it was what we call normal salt solution, but he was unable to state whether it was sterilized, or why it dropped out of use, but supposed it was for no special reason. He employed it exclusively at present in washing out the abdomen.

Dr. McBurney said he had had Frazer put up in bottles, stopped with cotton, sterilized salt of just the weight required for a quart of water, and this, he believed, was now kept in stock for the convenience of surgeons who might order it. In regard to drainage through the vagina, suggested by Dr. Cleveland, while it might be the best method in gynecological cases, he thought it was not indicated in appendicitis, since in the latter condition the tube was left in only twenty-four hours, and if allowed to remain longer did harm, causing a fistulous tract. If the suppurative process were in the pelvis he would rather drain in that direction, as suggested by Dr. Cleveland, but in appendicitis, the abdomen open, it was best to drain with gauze as had been described in the paper.

Dr. McBurney thought that a study of these cases with relation to the length of time during which the disease was apparently very simple, and then changed to a violent form, was more important than seemed to have been appreciated. His experience had been that the ugly pathological lesions had preceded by hours the symptoms which indicated them. For instance, a patient had apparently a mild inflammation of the appendix; after a time, say thirty-six or forty-eight hours, some additional symptoms became manifest, say greater pain over the lower part of the abdomen than had existed an hour or so before, the pulse became a little more frequent, perhaps there was some rise of temperature. He believed it was very common for medical men to recognize this change, but as the symptoms still remained slight, they failed to appreciate the very great importance of it. They did not realize that the change in the symptoms was due to a change in the lesion which had occurred some hours before. A patient who had a quantity of fluid run down into his pelvis did not at once have increased pain. Greater pain would not come until some hours afterward. Neither were the temperature and pulse affected at once. This meant that when such a change took place one should operate quickly, and not wait until next morning or some other time. It was delay which had been the chief cause of the fatal issue in a number of cases operated upon. It seemed to the speaker that the insidious way in which the ugly forms of appendicitis under discussion changed from a simple character to a very complicated and grave one, pointed very strongly indeed to the necessity for quick action at the very earliest point of change.

Acute General Miliary Tuberculosis.—Suppurative Arthritis.—Dr. Beverley Robinson reported the following case under this heading:

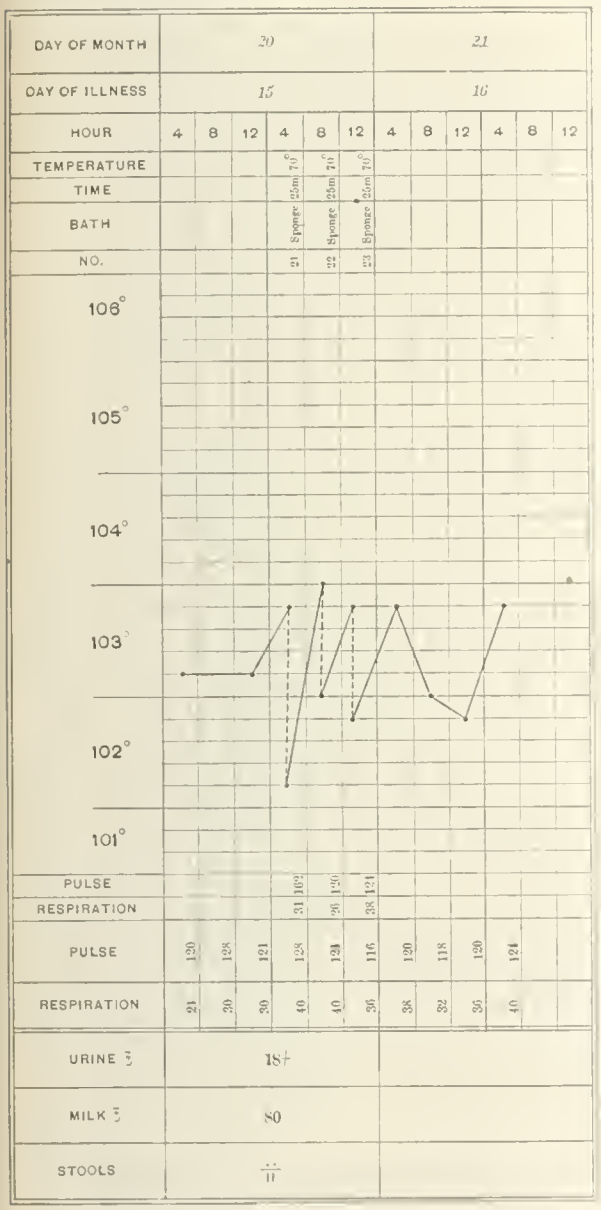


Joseph H——, aged thirty-four, laborer. Family history: Father, mother, and one sister rheumatic. Personal history: Marked alcoholic gonorrhœa a number of times, last four years ago. Doubtful syphilis. Chills and fever in Jersey seven years ago. Otherwise negative, except that patient has been drinking very hard for several months.

Present trouble began seven days ago, with pain in right knee, very severe, loss of appetite, and general malaise. Patient kept at work up to yesterday, feeling generally miserable, suffering from pain in both knees and loss of appetite. Two days ago had a distinct chill lasting an hour; yesterday had a headache, was nauseated, and felt chilly or feverish all day long. Bowels have been constipated. Chief complaint is pain in right knee and general malaise. Patient well nourished, good color. Face and trunk pitted and small cicatrices. Cicatrices on right side of neck, result of an adenitis. Heart apex fifth space inside of nipple line;

faint systemic murmur over apex transmitted a short distance to left; second aortic accentuated. Lungs, negative. Liver, dulness to one-half inch below free border. Edge felt here. Spleen and abdomen negative. Suppurative glands slightly enlarged. One or two faint rose-colored spots on abdomen and back, disappearing on pressure. Right knee rather hot to the touch, slightly swollen, patella floats. Some tenderness and pain on motion, also slight pain on moving hip. Tongue thickly coated with white fur and slightly tremulous. Pulse, regular, full, soft. Urine acid, specific gravity, 1.130; five per cent. hyaline casts. Milk diet and calomel stat.

November 14th.—Tincture of strophanthus, 5 minims, three times a day. Pain in knee and headache severe. Patient very restless.



November 15th.—Salicylate of soda, ten grains every four hours. Leucocytes, 6,000; urine acid, specific gravity, 1.030; albumin, ten per cent.; hyaline and granular casts. Hot pack given. Local application to knee.

November 16th.—Patient delirious during night and at times during day. Stop salicylate of soda. Hydrochlorate of quinine, three grains every three hours. Spleen percusses large. For sponges, see temperature chart. Bowels are constipated.

November 17th. — Urine acid, specific gravity, 1.030; albumin, twenty-five per cent., hyaline and granular casts. No Ehrlich. Right knee very much swollen, patella floats and distinct fluid were made out. Ice-bag applied. Knee is very painful and patient is restless and delirious. Nauseated and vomiting. Stop hydrochlorate of quinine. Salicylate of soda, ten grains every four hours.

November 18th.—Urine acid, specific gravity, 1.028; albumin, thirty per cent., hyaline and granular casts. Whiskey one-half ounce after sponge baths. Condition same, but delirium increasing.

November 19th.—Patient wildly delirious during night. Marked strabismus of left eye. Pupils contracted, right the smaller. Conjunctivæ congested. Skin slightly cyanotic. Pulse irregular. Leucocytes, 145,000. Patient in alternating stupor and delirium all day. Pulse, very irregular. Right pupil smaller than left. Fluid in knee found to be purulent serum. No tubercle bacilli found.

November 20th.—No change in condition. Distinct tenderness in back of neck, pain and rigidity on flexing head. Tache cerebrale present. Slight rigidity of limbs most marked on right side. Strabismus in left eye more marked. Bicarbonate of soda, ten grains, water, two drachms; lemon juice, one drachm with ice, every two hours; fluid extract of ergot, one-half ounce every four hours. Urine acid, specific gravity, 1.025; hyaline and granular casts.

November 21st.—Patient still remains delirious, his condition is no better. Knee-joint more swollen. Examination of eyes by Dr. C. S. Bull. Fundus normal in each eye. Strabismus thought to be due to irritation of left sixth nerve. Patient transferred to surgical service, where the following notes were made:

Suppurative Arthritis of Knee—Pyæmia—Acute Endocarditis — Suppurative Pneumonitis — Suppurative Nephritis.

November 21st.—Operation by Dr. Curtis. Two incisions were made, one on each side of patella, down to the joint; also two smaller incisions on posterior aspect of knee. A large quantity of pus was evacuated. The wounds were thoroughly irrigated with boro-salicylic solution. Drainage was provided for by three rubber drainage-tubes and several wicks of iodoform gauze. Iodoform gauze and bichloride dressing applied. Whiskey, one-half ounce every two hours.

November 22d.—Twitching of muscles of face and arms. Strabismus unchanged, little stiffness of neck. Entire dressing, packing, and drainage-tubes removed. Wound irrigated with boro-salicylic solution, one-half strength. Drainage-tubes cleaned and replaced. Packed with iodoform wicking; iodoform gauze and bichloride dressing applied. Urine acid, specific gravity, 1.020; albumin, five per cent.; no sugar; microscopic examination negative. Apply ice-cap. Patient extremely restless.

November 23d.—Very restless and somewhat delirious. Dressed as before. Little discharge. Pulse increasing in rapidity and somewhat weaker. Sponge for fifteen minutes at 70°, if temperature is above 103° F. Pulse weaker, more rapid, and irregular.

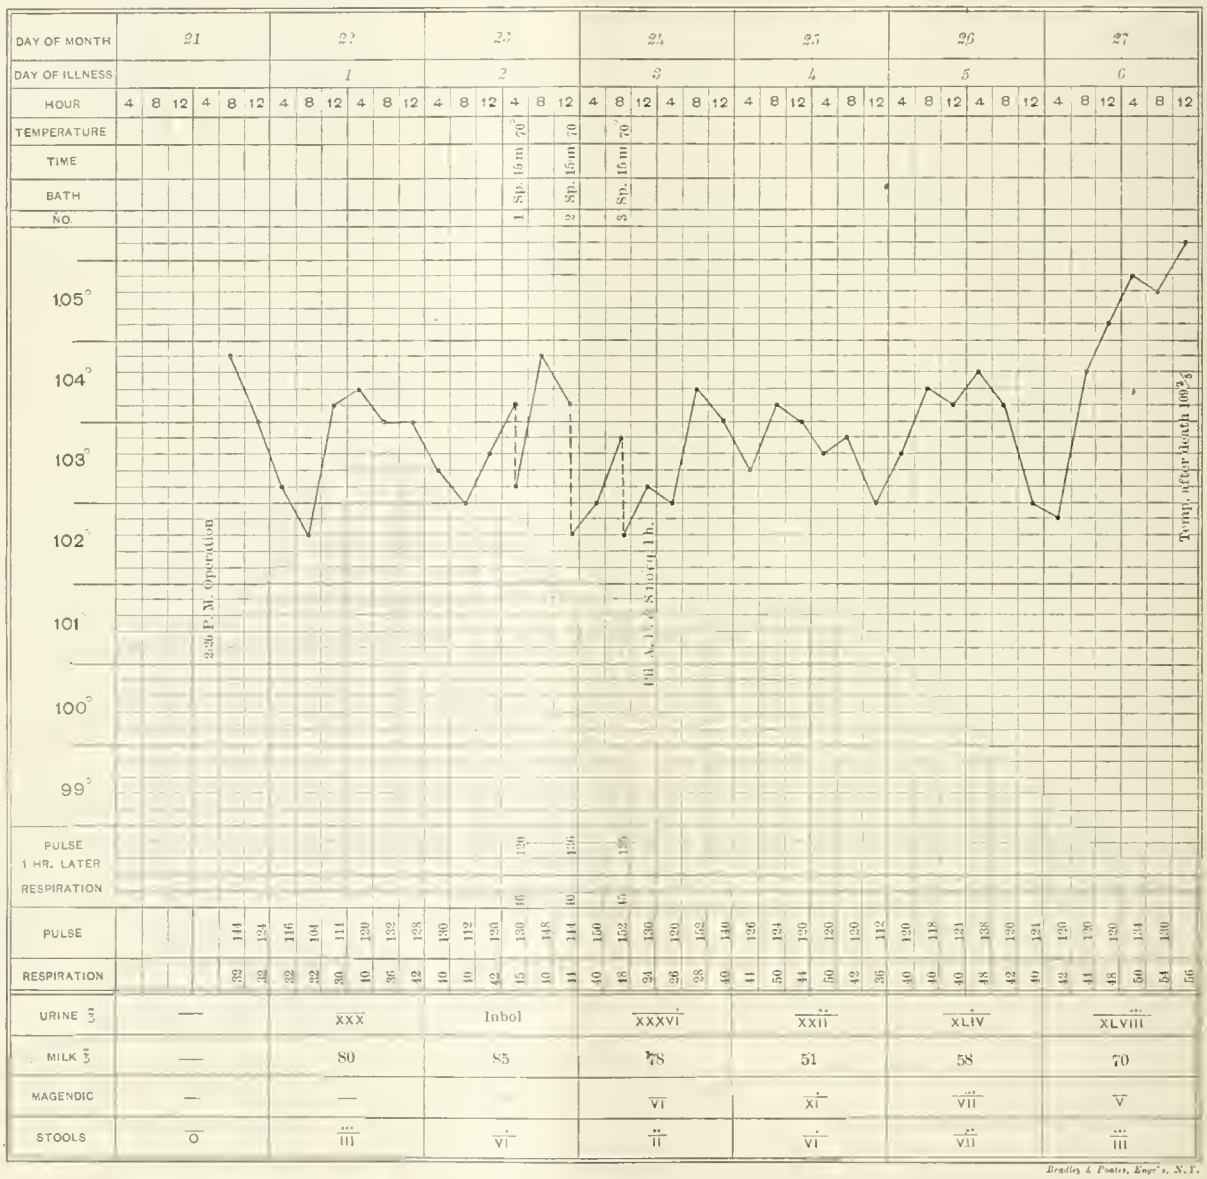
November 24th.—Patient has been restless and delirious most of night. Did not sleep at all. Whiskey one ounce every three hours. Fluid extract of digitalis five minims, hyp. stat. Trinity pill, No. 1, every hour. Stop when temperature is below 102° F. Lungs: Right, anteriorly resonance to sixth rib. Subcrepitant râles at end of inspiration, except in first two spaces. In axilla and posteriorly there is dulness beginning at angle of scapula and ending with flatness at last four inches at base. Here the breathing is feeble and there are crepitant and subcrepitant râles at the end of inspiration, with a few scattered areas of faint broncho-vesicular breathing. Lungs, left: Subcrepitant râles anterior and posterior. Posterior feeble breathing and subcrepitant râles with dulness at last three inches at base. Patient fairly rational. Vomited four ounces of undigested milk. Urine acid, specific gravity, 1.015; albumin, trace; no sugar. Leucocytes.

November 25th. — Respiration labored. Sputum streaked with blood. Cough a little troublesome.

Cups applied to chest. Usual dressing. Free discharge of pus.

November 26th.—Apex: Beat diffused over area of 2 by 2 inches. Here are heard inconstant rubbing and grazing sounds, synchronous with heart action. In left axilla there is good resonance, but many friction sounds. Otherwise signs in chest unchanged except that flatness in right posterior chest extends above angle. For past four days the abdomen has been moderately distended and tender. There is subsultus and occasional carphologia. To-day general hyperæsthesia. Strabismus unchanged. Moderate general rigidity. Usual dressing. Very slight discharge.

November 27th.—Patient much weaker and pulse feebler. Takes nourishment with difficulty. Ice-coil stopped.



November 28th.—Respiration labored and very shallow. Extremities considerably cyanosed. At 5.30 A.M. patient was very much cyanosed. Pulse almost imperceptible; and at 6.25 A.M. patient died quietly.

Autopsy.—Frame large; muscles well developed; adipose fair. Heart weighed nine ounces; recent patch of fibrinous exudation on anterior surface. Section shows normal heart muscle; just above attachment of cusp of tricuspid valve is a pea-sized nodule containing pus, running down about an inch in the muscle of the septum; abundant small vegetations on under surface of tricuspid and mitral valves. Lungs: Right, one pound; left, fifteen ounces. Left congested, especially lower lobe; few fresh adhesions in left lung and many on right lung. Many purulent foci in both lungs. Brain-pia congested and contains much serum. On section, some congestion. Gall-bladder contains pale yellow serous bile. Liver: Four pounds two ounces. Rather pale, with faint nutmeg markings. Spleen: Six ounces; rather soft. Left kidney: Ureter and adrenal normal, also pelvis; capsule free, surface smooth, color normal. Several purulent spots size of pin's head. On section cortex a little pale, markings fair. Right kidney the same. Meckel's diverticulum, three inches long, three feet above valve. Bladder, normal. No dictation on knee by Dr. Thacher. A large abscess ran up posterior aspect of knee-joint for about five inches.

The temperature had been very irregular, ranging between 101° and 106° F., averaging about 104.5° F.

Dr. Robinson said he had had such cases before, although not necessarily with joint suppuration; had found endocarditis at death, and had thought he would bear them in mind and make the diagnosis in subsequent cases, but the same experience had repeated itself.

Replying to a question from Dr. Draper, he said there was no history of recent gonorrhœal rheumatism.

Dr. Draper said the temperature chart in this case suggested to him a point which he had found of diagnostic value in endocarditis, namely, an up and down temperature several times a day. It was sometimes accompanied by chill, sometimes not. Some days

there were three or four paroxysms of fever, a thing which was not usual in any infectious fever with which he was familiar.

Grape Seeds in a Healthy Appendix.—Dr. McBurney presented a vermiform appendix containing two grape seeds, removed under the following circumstances: He was operating upon a patient for abdominal tumor; the healthy-looking appendix thrust itself into view, and on feeling of it he appreciated two concretions. Thinking it wise to act in time, he removed it, and the bodies which had been felt were found to be two grape seeds. The notion had been very prevalent that grape seeds were dangerous on account of their liability to lodge in the appendix and set up inflammation. Dr. McBurney had received letters regarding this matter from various parts of the country, a recent one being from a large horticulturist in the West, who said he would be greatly indebted to him if he could state that grapes were not dangerous. Dr. McBurney had always been able to reply that he thought grapes were harmless, since he had never seen a grape seed in the concretions contained within the appendix. It had so happened that the first exception to this experience was in a case in which he had incidentally removed the healthy appendix and found within it two grape seeds.

Dr. Polk remarked that he had seen grape seeds cause appendicitis in but one case.

Dr. Biggs made some remarks upon the work of the Board of Health in producing diphtheria antitoxin for use in the city.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, February 28, 1895.

Henry C. Coe, M.D., Chairman.

Hollow Cylindrical Uterine Dilator.—Dr. A. M. Lesser presented a set of uterine dilators, made of steel, cylindrical in form, and differing from the ordinary dilator in being hollow, the object being the avoidance of forcing the uterine contents into the tubes.

Dr. S. Marx thought the instrument could have no place in obstetrics, whatever it might have in gynecology; that in obstetrics the hand was the best dilator.

Improved Tarnier Basiotribe.—Dr. E. A. Tucker presented a modified Tarnier basiotribe, or combined perforator and cranioclast. The improvement related chiefly to doing away with some screw joints in the perforator, and in substituting a metallic for a wooden handle, thus aiding cleanliness. Without raising the question of craniotomy on the living child, it was well known that there were cases in which the operation had to be performed, and this he had found to be the ideal instrument for the purpose.

Modified Ligature Carrier.—Such an instrument was presented by a gentleman who failed to give his name, the modification relating to the spring and catch attachment.

Puerperal Septicæmia; Abscess in Right Broad Ligament; Abdominal Section Followed by Recovery.—Dr. Andrew F. Currier related the case. The patient had had a normal and easy labor, and everything had gone well until the fourteenth day, when she was suddenly seized with pelvic pain which increased almost to collapse. The following day a tumor appeared in the right iliac fossa, and went on to extend over to the left side. The doctors who saw the patient diagnosed hæmatoma. She afterward suffered from violent chills, diarrhœa, loss of flesh, etc. About two months after the confinement Dr. Currier saw her, and made the diagnosis of hæmatoma of the right broad ligament degenerated into abscess. Notwithstanding the patient's extremely low condition, he ventured to open the abdomen, first in the median line, but finding the intestines firmly adherent over the tumor, he made a lateral incision above Poupart's ligament, introduced the finger, broke down material which was too thick to wash out, then irrigated and introduced two yards of iodoform gauze. By venous infusion of saline solution and stimulants the patient was saved. A hæmatoma in what appeared to be a sealed cavity undergoing purulent degeneration, was contrary to what was usually taught. It was not improbable the infection had entered it from the intestine to which it was adherent.

Unintentional Induction of Abortion.—Dr. A. E. Gallant related a case in illustration of the difficulties attending the diagnosis of pregnancy. The case was one of cessation of menses for some weeks, then hemorrhage, the recognition of an enlarged uterus whose walls were flabby—circumstances leading to the diagnosis of abortion with retention of membranes. He introduced the sound, brought away fungosities, prepared for curettement next day, but found that soon after she had returned home a fœtus had been expelled. Dr. Gallant presented Outerbridge's combined dilator and irrigator, which he had found very useful in opening the cervix and washing out the uterus after curettement.

Ligature Carrier.—Dr. A. Goelet presented a modified ligature carrier, so made that the ligature could not slip as it did in other instruments.

Double-Current Uterine Irrigator.—Dr. Goelet also presented a double-current uterine irrigator, the important feature of which was its conical form, enlarging toward the end next the handle, and thus obviating tendency to become clogged by débris.

Dr. Garrigues had given up the use of double-flowing catheters, finding them unnecessary. In obstetric cases there was plenty exit for the fluid, while in other cases one could dilate and retain the cervix open with a speculum or dilator while irrigating with a single-current catheter. Larger débris would thus escape than with a double-flowing catheter.

Cœliotomy for Puerperal Septicæmia and Peritonitis.—Dr. Charles P. Noble, of Philadelphia, read the paper. He divided cases of puerperal sepsis, or puerperal peritonitis, into two classes: 1. Those in which some pathological condition existing in the pelvis before labor was the cause. 2. Those in which these organs were normal at the beginning of labor. In the first class sepsis might exist prior to labor, or be induced by bruising of the pathological tissue, or by causing rupture of pus-sac. In this class of cases operation was indicated, and if performed prior to labor promised a high percentage of recoveries. In a correspondence with a large number of operators, only three had stated that they had operated for peritonitis due to pus-tube which had been present before labor. The rarity of the complication was probably to be explained by the fact that few women with a pus-tube became pregnant.

The second class, those in which there had been no preceding pathological condition, was subdivided into those in which the infection spread to the peritoneum, etc., through the lymphatics and veins, and those in which it spread through the tubes. The author knew of no positive way to determine between the two classes, but he believed that where the infection spread through the tubes, the inflammatory element was more marked, the septic element less marked, the reverse being true in the other class of cases. In the lymphatic form the peritonitis was of secondary importance to septicæmia, and operation gave little encouragement.

Simple cœliotomy with washing out the peritoneal cavity did not influence the principal seat of the trouble, which was in the uterus and pelvic lymphatics, and necessarily it could not influence the germs which had already entered the circulation. The more radical operation of hysterectomy offered but little, since by the time peritonitis had become a marked feature either the patient was so reduced that she could not with-

stand the serious shock of the operation, or was already suffering from well-marked septicæmia. If operated upon it should be at the early stage, before the occurrence of peritonitis or marked general septicæmia. Cases with less marked symptoms of general septicæmia gave better results. While cases of general peritonitis, so far as he knew, had died when operated upon, yet he thought that in localized peritonitis cœliotomy should be done the first few days, if there were not prompt improvement under other treatment. In cases presenting well-marked local lesions which could be made out on bimanual palpation, the indications for operation were more urgent than in those in which nothing could be determined by physical examination. In other words, he thought the operation should be done or rejected according to the conditions found rather than according to general rules. The prognosis from operation was most favorable in local peritonitis where the inflammatory process had become well localized, sepsis being absent, the case having resolved itself into one of pyosalpinx or pelvic abscess of some form.

What should be done in cases of infection of the birth canal when, in spite of curettement, irrigation, and drainage, the disease went on from bad to worse? Cases in which septic infection or beginning septicæmia were marked features of the absorption of ptomaïnes or micro-organisms taking place from the uterus or vagina, while cellulitis and lymphangitis were absent or in their incipiency? Some years ago treatment would have been continued by irrigation or internal medication. But in the great majority of the cases the issue was fatal. Abdominal hysterectomy had been performed by Kelly and Smith with success, while Montgomery had lost his patient, and pus was found in the uterine sinuses. Dr. Noble would defend the operation in this class of cases. Regarding the route to be chosen, he thought that in puerperal cases it was usually best to enter above the pubes.

Prefers the Vaginal Method.—Dr. H. J. Boldt agreed with the author in the main, especially with regard to the hopelessness of operative procedure in puerperal general peritonitis and septicæmia. In localized peritonitis of puerperal origin he thought no one would dispute the fact that operative interference was indicated, and for his own part he would choose the vaginal route as the one which caused least shock and offered the best drainage. Pathological conditions existing prior to labor belonged to ordinary gynecological work, and called for operation.

Opposes Operative Interference.—Dr. William T. Lusk had seen three cases of tubal trouble present before confinement, complicating the puerperium, and when to-day he looked back upon the experience, which occurred some years ago, he wondered whether the patients could not have been saved by an operation. He thought it was very questionable whether, in the usual forms of puerperal infection, operative interference was ever justified before the tenth day. As the author had stated, in general septic peritonitis the patients died anyway. In other cases, where the disease was localized, he thought it would be better to treat them in the old way; many would get well, and if an operation should be called for it could be done with greater safety after five or six weeks than during the confinement period. There were a large number of cases of so-called septic endometritis in which the infection was limited to the mucous membrane, there was fever for about a week, and the patients recovered if let alone. If, however, the curette were used, and irrigation practised frequently, as had been done, the barrier offered to the entrance of micrococci by leucocytes in the infiltrated membrane would be broken down, and general infection would result. He, therefore, opposed the use of the curette in such cases.

Pathological Distinctions Easier than Clinical.—Dr. W. M. Polk thought the strongest criticism which could be offered against the classification was that it suggested distinctions which might be accepted in pathology, but which were not easily recognized at the bedside. In opposition to what Dr. Lusk had said, he felt very strongly the need of losing no time in reaching the interior of the uterus in cases of puerperal fever, cleansing it thoroughly either with the finger or curette, and providing for ample drainage by the introduction of gauze.

Regarding further interference, it was difficult to decide clinically which cases called for hysterectomy, or at what stage. He presented the uterus removed four days ago for puerperal sepsis, but it was too late and the patient died. The treatment, then, was to attack the interior of the uterus first, and if the symptoms did not subside one was then at liberty to open the abdomen, but it should be remembered that this, as a last resort, did not promise a great deal. He had saved one patient by cœliotomy without hysterectomy, operating not later than the seventh day. In pus accumulations existing before labor operation was indicated.

Dr. H. J. Garrigues thought laparotomy would have an extremely limited field in puerperal affections. He would hardly care to take the responsibility of opening the abdomen the first two or three days, as suggested in a certain class of cases by the author. It was known that many patients with bad forms of puerperal peritonitis recovered without operative interference, and he doubted whether the surgeon could secure a better result. Some years ago he had saved seven out of thirteen cases of general peritonitis by enormous doses of opium. He believed in cleaning out the uterus, preferably by hand in fever after labor at term, by instrument after abortion and cleansing with antiseptic injections.

Dr. W. E. Porter thought a large percentage of cases of puerperal fever could be saved by early removal of septic matter from the interior of the uterus, but unfortunately the specialist was not usually called until the disease was advanced. If cœliotomy were done at all it should be limited to irrigation and drainage. Hysterectomy would cause shock out of proportion to the amount of sepsis removed with the uterus.

Dr. Ralph Waldo thought very bad cases, mentioned in the paper, would die whether the abdomen were opened or not, while others treated in time by emptying the uterus, irrigating, and draining, could be saved without laparotomy. Of course an operation was sometimes called for to remove local accumulations of pus.

Dr. Ford, of Philadelphia, impressed the fact that the source of infection varied in different cases, being, in some from a laceration of the vagina, in some from a laceration of the cervix or perineum, in others from absorption within the uterus, and it was not easy to decide when operative interference was called for. He related a case of extra-peritoneal pus collection similar to Dr. Currier's, treated successfully by incision over Poupart's ligament.

Dr. Brooks H. Wells related a case seen by him fifteen months ago. The attending physician had delivered the patient with forceps; sepsis followed; he curetted four or five times, at intervals of five or six hours, without antiseptic precautions; the patient grew steadily worse, the temperature went up to 106° F., and Dr. Wells was sent for when she was in collapse. A mass was felt in the right side of the abdomen, and although the patient was almost moribund he decided to operate, which he did in a tenement-house. On opening the abdomen he found that the uterus had been perforated anteriorly. The vermiform appendix being unusually long, had become adherent across this perforation, thus proving a life-saver instead of a life-destroyer, in this instance. He cleansed out a collection of pus with the sponge and introduced gauze, and to his surprise the patient recovered. The right tube, which had lain over the abscess, was perfectly normal.

Dr. E. A. Tucker said that his experience had shown the wisdom of Dr. Lusk's remarks. Out of about four thousand cases of labor which had passed under his observation, there had been puerperal fever in 150 or 200, and he could recall not more than one in which laparotomy might possibly have been done with benefit. Later operations for pus collections, say a month after labor, should not be spoken of as cœliotomy for puerperal sepsis.

Dr. Currier remarked that most cases seen by gynecologists had previously been treated by the general practitioner, and were not very recent, yet he thought they should not be excluded from consideration as puerperal cases. There was such a variety of conditions that it was not easy to make exact classifications, yet he thought three main types might be recognized: 1, Cases in which the infection was limited practically to the uterus; 2, those in which it had extended into some neighboring structure, but was limited; 3, those in which there was diffuse peritonitis. Laparotomy was excluded in the first variety, was to be considered in the second, was hopeless in the third. Local pus collections should be removed.

The Chairman, Dr. Coe, did not think the author had intended to raise the question of curettage and irrigation. Of course, Dr. Coe said, everybody resorted to those measures. He had not arrived at the stage where he would remove the uterus, although he had been tempted to do it twice. There were a good many cases of pus collection the first week after childbirth, and he would not exclude them from consideration as puerperal cases, as he had understood Dr. Tucker to suggest. In one instance he had emptied a pus collection which had extended up to the umbilicus the first week, and in another instance where he had found it under the lower rib. He supposed the author had not intended to limit the term cœliotomy in this discussion to median incision.

Dr. Noble, in some concluding remarks, said that if after curettage, douching, and putting in gauze, the patient went on to get worse for twelve or twenty-four hours, the septic symptoms becoming more marked, he thought all would acknowledge that the case would terminate fatally unless something more were done, and it was under those circumstances that he would perform hysterectomy. Peritonitis and general septicæmia had not yet become marked. The chances for the surgeon to win laurels were not great, but operation gave the patient about the only chance.

Clinical Department.

REPORT OF A CASE OF SEPTIC POISONING FOLLOWING THE USE OF ANTITOXIN.

By EDWARD J. WARE, M.D.,

NEW YORK.

In the Medical Record of January 19, 1895, an article by Dr. A. Seibert, gives an account of the toxic effects of antitoxin treatment which are so very similar to those occurring in a case of my own, and yet having some points of marked contrast, that I deem it of interest to note them.

The patient, Elizabeth B——, aged three years and four months, had not been well for two weeks previous to the present illness—having had a persistent cold and so-called "bilious condition," with clay-colored stools, loss of appetite, and general malaise.

On December 21st, the child was constipated and had fever. She was first seen by me December 22d. Temperature, 103° F. (groin). Child peevish and somnolent; tongue coated; some pallor and loss of appetite. No swelling of the glands, and the throat absolutely clear and hardly injected; some coryza; no fetor to breath.

December 23d.—In the morning slight deposit on left tonsil. Glands of neck slightly swollen. Temperature, 102½° F. (groin); afternoon temperature, 103½° F. Child restless and depression marked. Ordered tincture of chloride of iron and whiskey in full doses.

December 24th.—Deposit decidedly more marked on both tonsils, and decidedly diphtheritic in appearance. Some albumin in urine. Temperature, 102½° F. At 8 P.M., 11 c.c. Pasteur's serum were injected in loin.

December 25th, 8.30 A.M.—An injection of 10 c.c. serum was given. In afternoon, temperature (axilla) 98° F. The throat gradually cleared. Temperature was uniform at 98° from December 25th to 30th. Swelling of glands diminished—albumin was disappearing.

December 31st.—Throat was practically clear and convalescence appeared to be established. Pulse ranged from 96 to 106. Iron and whiskey were continued throughout.

January 5th.—In afternoon, temperature was 99.6° F., and there was slight swelling of glands on left side of neck behind sterno-mastoid muscle.

January 6th (thirteen days after injection).—Glands were swollen on both sides of neck in corresponding location. Temperature, 101.4° F.; pulse, 112. A discrete eruption of raised, flat papules appeared on buttocks. They were of rather dusky-red color, closely resembling the eruption caused by antipyrine. There was no rigor; there was, however, some stupor, somnolence, depression, and loss of appetite. Child complained that eruption hurt, which probably would be better described as itching or burning. There was, also, a general hyperæsthesia of the whole surface; but no distinct joint swelling or pain as in Dr. Seibert's case. The temperature ran to 102.2° F. (its highest point), with pulse of 145 and respirations of 33.

January 7th.—Temperature ranged from 99.9° to 101.8° F. Pulse, 118 to 130; respirations, 28 to 32. The rash next extended to thighs, legs, and feet; then attacked the hands and arms, face and neck; lastly extending from buttocks on to the back, abdomen, and chest. It was more marked on back and chest, and was generally discrete in distribution, although there was coalescence at times, with large, white, clear areas, such as we see in measles. The general appearance varied but little. The papules were large—flat and raised—varying in size from that of end of slate pencil to the size of a silver three-cent piece or larger. The color was dusky-red. There were no vesicles or pustules. The hands, forehead, arms, and face showed considerable œdema. During all this time the throat remained perfectly clear, and there was never a suspicion of return of the exudate. The urine was almost completely suppressed and the amount of albumin much increased. This was relieved by cupping the loins and the use of the hot pack.

January 8th.—The temperature ranged from 99.8° to 102° F.; pulse, 104 to 122.

January 9th.—Temperature from 101.2° to 102.2° F.; pulse, 118 to 130.

The rash lasted from three to four days. The first papules appeared on January 6th, and the skin was practically clear on the 10th. As each new crop appeared there was a rise of temperature.

January 10th.—Temperature at 1.50 A.M. was 101.2° F.; at 8.45 A.M., 98.2° F.; at 1 P.M., 98° F.; at 7.40 P.M., 96.2°. At this time (7.40 P.M.) pulse was 100, fair in quality. Second sound of heart very indistinct; feet and hands cool; ordered whiskey, ammonia, and hot beef extract.

January 11th.—Temperature ranged from 97° to 97.6° F.; pulse from 96 to 106. Ordered tinct. nux vomica one drop every four hours; increased to two drops at 2 P.M. Pulse somewhat better and sounds clearer.

January 12th.—Temperature, 97° to 97.4° F.; pulse, 99 to 102.

January 13th.—Temperature reached 98° at 5.30 P.M., with pulse of 100. General condition about the same.

January 14th.—Temperature ranged from 97.2° to 97.9° F.; pulse, 80.

January 15th.—At 9 A.M., temperature dropped to 96.2°, with cool extremities; some pallor and depression. At 10.30 A.M. temperature was 96.4° F.; at 12.45 P.M., 97° F.; at 3.15 P.M., 96.4° F. From that time on it ranged from 97° to 97.3° until 9 A.M. on the 17th, when it again touched 98° F. At 6.30 P.M., temperature was 98.3° F.

January 18.—At 4.30 A.M. temperature was 97°, and from then on ranged from 97° to 98° F. On the 19th, at 4.45 P.M., it reached 98.2°, and from then on resumed normal.

These temperatures were all taken by axilla, the thermometer being left in position for fully ten minutes. This was done because it was found practically impossible to take it by rectum, as it caused too much disturbance.

On December 25th the child's mother had slight deposit on left tonsil, with slight chill and temperature. On December 26th there was also deposit on right tonsil. On that date 15 c.c. of serum were injected, and on the 27th 10 c.c. were injected. She was also ordered tinct. ferri chloride and whiskey, and irrigations with hot boracic-acid solution. Five days after the first injection she had an eruption appearing first on the toes and feet, and afterward on the hands and arms. This was described as being in wheals and welts, intensely itchy, burning, and stinging. It always appeared at night, and was so faded, or practically gone, in the morning, that I never saw it. This was repeated for three or four nights. It was not accompanied by any constitutional disturbance.

The points of greatest interest were the peculiar rash appearing at such a remote date (thirteen days) after the injection, and the subsequent subnormal temperature, which persisted almost continuously from January 10th to January 18th. Also the fact that the mother's rash appeared five days after the injection, was evanescent in character, and accompanied by no constitutional disturbance.

REPORT OF A CASE OF EXOPHTHALMIC GOITRE—TREATMENT—RECOVERY.

By FRANK D. BOYD, M.D.,

SAN ANTONIO, TEX.

The occurrence of this disease in the male is of such comparative rarity that I desire to report this case that has recently been under my care: Mr. R——, aged thirty-two. Previous to this general health was very good. First noticed mental excitement and rapidity of heart-beat in 1891, caused, he thinks, by financial reverses. He then went south to Old Mexico in the fall of 1891, and resided there a few months. Travelled over the interior of Mexico in railroad-coach and horseback at altitudes varying from five thousand to ten thousand feet without apparent inconvenience, sometimes climbing in the saddle three thousand feet in one hour's time with no unpleasant feelings. Then in the spring of 1892 he returned to an altitude of seven thousand feet and went in the banking business, and at this time he first noticed a continual nervousness, much worse at times than at others, becoming almost uncontrollable when anything unusual happened. Any mental worry would cause great nervousness. Also noticed a general decline in health. Appetite became very bad; would have bilious attacks at repeated intervals; impairment of digestion. In October, 1892, he first noticed the neck began swelling and eyeballs protruding, which reached their maximum December 1, 1892.

I was called in to see patient in February, 1893, and found him suffering from an exaggerated case of mucopurulent conjunctivitis in both eyes. I soon discovered the great protrusion of eyeballs, and on closer examination found I had a typical case of exophthalmic goitre to deal with. The thyroid gland was greatly enlarged. Pulse reached 150 beats per minute, and he was very excitable. He then told me the above history, and also of his having fallen a few weeks previous. "The lower limbs simply giving down." He is a man of very strong intellect and I had no trouble in securing a good history. He gives no family history of this trouble. His mother is still living in good health. His father died a number of years ago from other trouble. I saw that he not only needed my services, but a general physician, so he called his family doctor, Dr. F. M. Hicks, and we together have had him in charge since. The inflammation of the eyes soon subsided. The treatment consisted of iodide, hydriotic acid; infusion of digitalis; galvanism daily over the thyroid; freedom from business of any kind; complete rest mentally as much as possible, and also physically, which is very essential. The home and surroundings were very pleasant. When excitement would be very great would apply ice-bags to thyroid. Result of the treatment has been very satisfactory. There has been a general improvement in every respect. Protrusion of eyeballs greatly diminished. Pulse average beat now from 80 to 90. No excitement; very calm. Thyroid much reduced, so can button collar of shirt easily. He has now resumed work.

PERIOSTEAL INDURATION OF THE MAXILLA RESULTING FROM EXOSTOSIS OF TOOTH ROOTS.

By CHARLES G. PEASE, M.D., D.D.S.,

NEW YORK.

LATE LECTURER ON MATERIA MEDICA, THERAPEUTICS, AND PATHOLOGY, IN THE NEW YORK DENTAL SCHOOL.

I have been influenced, in presenting this short paper, by an appreciation of the fact that these conditions are not fully understood by the average practitioner, who finds it difficult or impossible to make an accurate diagnosis, owing to the obscurity of the primary conditions.

The recital of a recent case to which I was called in consultation, will give a clinical aspect to the subject, far more helpful than treating of it in general.

Mr. K——, aged twenty-eight, had been under treatment for some weeks for swollen face with abscess, for which no apparent cause had been discovered. Patient had lost twenty-five pounds in flesh, had grown sallow, depressed, and nervous. No appetite. Abscess had been freely lanced.

On examination externally, I found a hard indurated tumor on a line with the lower maxilla, left side, extending from the angle of the jaw to a point identical with the six-year molar. Within the oral cavity I found an abscess discharging at a point opposite the buccal aspect of the twelve-year molar. By the use of the probe I was not able to satisfactorily determine the origin of the trouble.

The teeth were sound so far as caries was concerned, and by the use of a small piece of ice applied to the teeth separately, I was able to exclude devitalized pulps, each tooth giving the response indicating vitality. There was no soreness on tapping the teeth, and the patient had no pain or soreness associated with them either just before or during the existence of the tumor. The masseter muscle would not relax fully, but sufficiently to make examination. My interrogations were then put with reference to the history of the wisdom-tooth, and I learned that its eruption, eight years previously, had been accompanied with soreness and swelling, which signified little, as these conditions are very often present as concomitants.

Four years after eruption of the wisdom-tooth there had been a hard swelling at the angle of the jaw, which shortly disappeared. Being able to exclude all other teeth and surrounding tissues, I advised the extraction of the wisdom-tooth, which I did, and found the roots much thickened by exostosis, and at the apex of the distal root a spicula as sharp as a needle. Patient made a rapid recovery.

The writer has treated quite a number of these tumors, invariably in connection with the lower jaw. He does not think they are often found in the superior. Such chronic conditions being in the latter relation more apt to induce caries, which disease is known to be as uncommon to the lower as it is common to the upper jaw. The tumors either remain fixed in character after growing to the size of a walnut, or in very bad subjects they degenerate into abscess, and, discharging thus the offending body, correct themselves. This is possible where the septic gases of a devitalized pulp is the cause, but not in the case cited. Such spontaneous cure is, however, not common.

If the diagnostician will keep exostosis of the tooth roots in mind, especially with relation to the wisdom-tooth, it may help him in perplexing cases.

101 West Seventy-second Street.

LARGE DOSES OF MORPHINE.

By W. A. CLARK, M.D.,

Resident Physician of Alameda County Infirmary, San Leandro, Cal.

The following is the history of a case in which I failed to obtain any narcotic effect from some quite large hypodermic injections of sulphate of morphine.

Mrs. M——, aged sixty-seven, widow, no children, laundress. About two years ago was given several hypodermic injections of morphine for severe abdominal pain. Powders containing the drug were soon substituted and gradually increased, until before her death she was consuming twelve grains of morphine daily.

January 16th.—Aneurism of abdominal aorta diagnosed, and being in considerable pain, she was given the following :

℞. Morph. sulph. ..... gr. xxx.
Aqua ..... ℥ iv.
Sig. : Teaspoonful every quarter-hour until relieved.

The hospital steward being called during the night, gave the following quantities at quarter-hour intervals : One-quarter grain, hypodermatically : four grains by the mouth : two grains, hypodermatically : three grains respectively ; no result.

January 17th.—Remedy repeated as before. I was called about 7.30 P.M. and found her in intense pain. I gave the following quantities hypodermatically, at quarter-hour intervals, commencing at 8 P.M.

Three grains, five grains, seven grains, in two injections, eight grains in two injections, six grains ; no effect. Eight grains by the mouth was then given until 11 P.M., when the stock on hand gave out, making a total of eighty-three grains consumed in three hours, with no appreciable effect. The sulphate of morphine had been prepared by a reliable firm, one-quarter grain from the same bottle giving a full effect in another patient. I might add that she had been consuming, daily, eight ounces each of whiskey and port wine, and a quart-bottle of beer, until about two weeks before her death, which occurred January 21, 1895.

At the post-mortem examination no aneurism was found. Under the right kidney half of a hair-pin old and corroded was discovered, with considerable localized peritonitis and old adhesions.

Medical Students in France number over ten thousand. Their number has more than doubled in the past ten years.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ANNUAL MEETING OF MEDICO-CHIRURGICAL SOCIETY—SPECIAL DISCUSSION AT PATHOLOGICAL SOCIETY—TRACHEAL DIPHTHERIA—MALFORMATION OF HEART WITH HÆMOPHILIA—GANGRENOUS UMBILICAL HERNIA—LIVER AND GALL-STONE SURGERY—MICROCEPHALUS.

London, March 6, 1895.

Societies are very much *en évidence* just now. On Friday the Medico-Chirurgical held its annual meeting, when the alterations in the by-laws that have been officially proposed with a view of rendering the meetings more popular, were duly passed. The president, Mr. Hutchinson, gave his annual address, in which he alluded to the losses by death during the year, and to the changes now made to adapt the society to the condition of the times. The exhibition of patients and specimens, and detailing of new facts, is among these. So is the arrangement for special discussions on topics of general interest, which might not otherwise come up in an original paper. As to these I have previously reported that the first such discussion has been already opened by the president himself, on the nervous complications of early syphilis. This debate has been adjourned until next Tuesday. Meantime another special discussion has been provided for us by another society—the Pathological. This was opened by Dr. Bertram Hunt last evening, who was followed by Drs. Hayward, Powell White, and Kanthack, when the debate was adjourned to the 19th. The subject being the "pathology of diphtheria," is of immediate interest and is being ably discussed.

At the Clinical Society on Friday, March 1st, Mr. Langton, vice-president, took the chair, saying he had been requested by the council to fulfil the duties of president until the end of the session. He gave appropriate expressions to the loss inflicted on science, on surgery, and on the society by Mr. Hulke's death, and the society passed a formal vote of regret.

Mr. E. W. Goodall related an unusual case of tracheal diphtheria in a boy aged four, who was admitted into the Eastern Hospital with faucial diphtheria. On the ninth day after admission he expectorated a cast of the trachea, and during the next week he brought up several casts of the trachea or bronchi, and several shreds of membrane. There was albuminuria lasting for about a month. At the end of three weeks from admission paralysis of the palate, ciliary muscles, and lower extremities supervened. The boy recovered and left the hospital quite well at the end of another seven weeks. The point of interest in the case lies in the fact that, in spite of the extensive formation of membrane in the trachea and large bronchi, there were never signs of laryngeal obstruction. Only during the expulsion of the largest casts was there dyspnœa. It is reasonable to suppose that in this case the larynx was unaffected. Three similar cases had come under observation. He particularly called attention to the fact that the membrane missed the larynx, though it affected the respiratory tract above and below. Some conversation followed in which the relation of such cases to plastic bronchitis was referred to. Dr. Lee Dickinson related a case of malformation of the heart in a girl aged eight, with pronounced congenital heart disease and hæmophilia, and asked how far these diseases are related. The hemorrhage could not be explained by reference to the heart trouble only. The condition of the patient was not usually met with in subjects of congenital heart disease, the child not being cyanosed while under his observations, though this was said to have been the case once or twice. There was no club-

bing of the fingers or other indication of chronic circulatory trouble. There was no history of hæmophilia in the family.

Mr. Gilbert Barling related a case of gangrenous umbilical hernia in a female, aged forty-nine, for which resection was performed and immediate union effected by Murphy's button. She was admitted to the hospital four days after strangulation commenced. On the day of admission symptoms ceased suddenly. Strangulation was by a severely constricting band which involved about five inches of small intestine, and the upper or entering portion was gangrenous at the point of constriction. The patient's general condition being good, the strangulated gut, with a V of mesentery, was removed and the divided ends of the intestine approximated by a Murphy's button one inch in diameter. Recovery was uneventful, but the button was not passed until the twenty-fourth day, two days after the patient had been allowed to get up. It gripped a ring of necrosed gut.

Mr. A. Pearce Gould commented on the curious absence of collapse in this case, and suggested that the symptoms of "indigestion" from which the patient suffered subsequently to the operation might be explained by the arrest of the button at the ileo-cæcal valve.

The president referred to the tendency of stenosis to which patients were exposed after using Murphy's button, Senn's plates, and the like. The length of the operation in such cases must necessarily have an effect on the patient's condition. He asked how long the operation had lasted. He did not agree with certain surgeons of the German school, who held that these operations did not necessarily involve any collapse.

Mr. Barling, in reply, remarked on the difference observed in the way that patients reacted to peritonitis in illustration of the curious absence of shock. He pointed out that the "indigestion" occurred on the fourth day and followed the first ingestion of food by the mouth. That was earlier than one would expect the button to have become detached. He admitted that in some cases the button sojourned in the intestine an inconveniently long time, but on the whole he thought the risk of its becoming arrested in its onward passage was slight. The operation took fifty minutes.

Dr. Hector Mackenzie related a case of hysterical contracture of the legs of two years' duration, which had been cured by massage, etc., in a young woman of twenty-three.

At the Medical Society on Monday, February 25th, Mr. Malcolm related all the cases of liver and gall-stone on which he had operated. In three of these cases death followed, but the fatal termination was the natural sequel of the diseases from which the patients were suffering, and was in no wise attributable to the operation. The other cases comprised two of multiple hydatids, and three of gall-stones removed by operation. These five cases were all successful. He suggested the following points for discussion: 1. The signs to be relied upon in distinguishing between gall-stone and cancer. 2. The possibility of gall-stones being overlooked in the ducts, and the possibility of their collecting within the liver substance and coming down after the other stones had been removed. 3. The length of time which must elapse before a patient can be considered safe against recurrence of hydatid growths. 4. Whether the presence of shrivelled daughter cysts was a sign that the cysts were undergoing retrogression, in spite of the fact that there had been no diminution in size of the cysts previous to operation.

Mr. Doran asked how long gall-stones took to form, and Mr. Lane related four fatal cases, only one of which could be referred to the operation, and he had had a long series of successes.

Mr. Henry Morris discussed the diagnosis of hydatid cysts, and thought the formation of gall-stones was promoted by anything which interfered with the formation of cholesterin or by deficiency of the bile, and which were solvents of cholesterin. He believed that stones did sometimes form after operation with astonishing rapidity, which he thought might be due to a lack of such solvents, or an excess of this product as a consequence of stagnation of the bile in the gall-bladder.

Dr. Wallis Ord and Mr. Cottrell then read notes of a case of microcephalus treated by linear craniectomy.

Dr. Shuttleworth questioned whether the case was, properly speaking, one of microcephalus, seeing that the circumference of the head exceeded nineteen inches, whereas eighteen inches was usually assigned as the limit. He himself had had under observation three cases of microcephalic idiots in whom the operation had failed to confer the slightest benefit.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 23, 1895.

	Cases.	Deaths.
Tuberculosis	54	138
Typhoid fever	2	1
Scarlet fever	121	20
Cerebro-spinal meningitis	3	6
Measles	147	14
Diphtheria	216	35
Small-pox	1	0

Morbidity in the Indian Army.—According to a recent report concerning the British forces in India, no less than fifty thousand out of seventy thousand men composing the army have been under hospital treatment within the past two years.

A Gift.—Drs. A. V. L. Brokaw and C. D. Mooney have contributed one thousand dollars toward the completion of a clinical amphitheatre in St. Luke's Hospital, St. Louis.

Alumni of Jefferson Medical College.—Many members of the class of 1879, Jefferson Medical College, of Philadelphia, are desirous of having a class reunion on the occasion of the 15th anniversary of their graduation. Owing to changes, comparatively few addresses are known, and therefore this means is resorted to with the hope that every member of the class of 1879 who reads this notice will communicate at once with their class President, Dr. Philip R. Koons, Mechanicsburg, Cumberland County, Penn.

The New York Medical College.—A short sketch of this institution was written and printed in 1883, but has only just been published. It is of considerable historical value, and especially interesting to the not inconsiderable number of graduates of this college still engaged in medical practice. The sketch was written by Dr. Edwin Hamilton Davis.

Modern Greek as an International Language.—In the "Register and Manual of Information," published by the New York County Medical Association, we are pleased to see a recommendation that Greek be adopted as the common language of science. It is suggested that the medical writers of this city officially endorse the proposition to adopt this most beautiful, most flexible, and most expressive of tongues as the means of inter-communication between scientists throughout the world.

A Statue to Lavoisier is to be erected in Paris. Many subscriptions in aid of its erection have been obtained from professors and students of German universities.

PRACTICAL POINTS IN THE TREATMENT OF DIPHTHERIA WITH ANTITOXIN—INDICATIONS AND CONTRA-INDICATIONS FOR THE SAME, WITH DEMONSTRATION.[1]

By LOUIS FISCHER, M.D.,

NEW YORK,

INSTRUCTOR IN DISEASES OF CHILDREN AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; PHYSICIAN IN CHARGE OF THE MESSIAH HOME FOR CHILDREN; PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE GERMAN POLIKLINIK.

ALTHOUGH the new diphtheria-healing and prophylactic remedy called serum and diphtheria antitoxin, was discovered in 1890, it took until the last year to place it on a proper clinical basis, *i.e.*, by experimental work on both healthy and sick to determine the exact therapeutic properties of the same. In Berlin, Professors Behring, Wernicke, Hans Aronson, and a great many others have labored diligently to give us all the data relating to the same. It was, however, necessary to study the statistics and reports of the various hospitals in order to arrive at a proper understanding of the value of the remedy. It is hardly a year ago that we found so little in literature pertaining to the same, which was chiefly owing to the scepticism of the various colleagues, owing to the misfortune in using Koch's tuberculin in 1891. To-day, however, we have about two thousand two hundred authentic cases, which have placed the remedy on its proper footing. When I was in Berlin last summer there were two kinds of antitoxin for sale: Aronson's and Behring's; both, however, were almost sold. Since that time quite a change has come, and there is at present all the antitoxin desirable in the market.

Permit me to introduce to you the various kinds of antitoxin, and also some practical points about the same.

The first publication in this country appeared in the MEDICAL RECORD, October 6, 1894, by Professor Baginsky, and in the same number also one by myself. Later, reports appeared from Dr. A. Campbell White, of the Willard Parker Hospital, who reported twenty cases in the same journal (the MEDICAL RECORD, November 17, 1895); in the same number there appeared a second article by myself. In the cases of White, Aronson's serum was used only; in the cases which I reported, I have used also Aronson's; later, however, I used Aronson's and Behring's, as Aronson's was not to be had. In the *American Journal of the Medical Sciences* for January, 1895, a very elaborate article appeared by me, describing thirty-four cases, and also a series of cases which I attended in the Municipal Hospital of Philadelphia. In that class of cases I used principally Aronson's serum, and my mortality was 5.8 per cent.

Permit me to describe a few typical cases.

CASE I.—A. G——, three and one-fourth years of age, male, was attended by me on October, 29, 1894, in the Messiah Home for Children. Examination showed hoarseness, normal temperature, regular pulse. The throat, as far as we could see, tonsils, pharynx, and uvula, was clear. No membrane was visible. I ordered isolation and expectant plan of treatment. I could not diagnose anything but acute laryngitis. The following day, however, October 30th, I again saw the child, and found the following clinical picture: Severe dyspnœa, very plain pseudo-membranes were visible on the pharynx posteriorly, and on the right tonsil. Temperature, 100° F.; pulse, 104; respiration, 82; no cyanosis. The submaxillary glands somewhat enlarged. Symptoms of general malaise. The child appeared very tired and sleepy. Stools were regular. As we here had reason to believe that we were dealing with a very early form of diphtheria and laryngeal stenosis, and as this case was one typically suited for antitoxin treatment, I sent the child to the Willard Parker Hospital, with a letter, stating that I wished this case reserved for treatment by Dr. George F. Shrady. I went to the hospital with him at 1.45 P.M., October 30th. Found temperature 100.2° F.; pulse, 130; respiration, 32. Child was injected by him with 12 c.c. antitoxin. At 2.25 P.M., dyspnœa was so severe that it was necessary to intubate the child. Soon after the breathing improved. At 3.25 P.M., temperature 101.8° F.; pulse, 140; respiration, 32; 5.25, temperature 103° F.; pulse, 160; respiration, 48. The child seemed to swallow in the regular way. The reaction following intubation disappeared slowly during the night.

The highest temperature during October 31st was 102.4° F.; pulse, 144; respiration, 44. The temperature remained under 101° F., until November 4th, on which date a small quantity of albumin was found in the urine. The quantity increased until it reached twenty-five per cent. by volume. On November 5th the temperature was 103° F.; pulse, 148; respiration, 40. On November 5th the membranes disappeared. The child coughed with a muco-purulent expectoration, which was, however, not very severe. On November 7th there were slight traces of albumin in the urine; the temperature sank to 99° F. Intubation tube was removed on November 7th, at eleven o'clock in the morning. The breathing was at once labored and it was necessary to reintubate the child in a quarter of an hour, at 11.30 in the morning. There was hardly any reaction following the reintroduction of this cannula, and the temperature did not rise above 99° during the day. On November 8th the temperature was 99° F.; pulse, 134; respiration, 32. The child seemed to feel very well during the course of this treatment, and had no emaciation, no loss of flesh, and was discharged cured. The healing was complete in this case.

Bacteriological examination of the membrane was made on October 31st, or the day following the child's admission to the hospital, and typical Klebs-Loeffler bacilli were found, proving the diagnosis of diphtheria. The child was subsequently carefully examined by me, readmitted to the Messiah Home, and here a slight form of paralysis followed, lasting in all about two months. The fluids on swallowing regurgitated through the nose. With mild form of treatment, principally strychnine and faradization, the child made a complete recovery.

Another typical case is the following: I was called in consultation by Dr. A. Kessler, on December 10th, to a boy, about six years of age, who had been attended by the doctor for several days previously, with a severe pharyngeal, tonsillar, and laryngeal diphtheria. The

[1] Paper read at the German Medical Society, March 4, 1895.

whole pharynx showed thickened membranes completely covering the throat; besides, the child appeared to be somnolent most of the time. This latter symptom proved to Dr. Kessler the severity of the case. When I saw the child, on December 10th, it was at once decided to inject antitoxin. Owing to the severity of the symptoms I decided to inject 20 c.c. of the same, using the ordinary aseptic precautions, consisting of sterilization of the skin with soap and water, followed by an antiseptic solution, and injecting the antitoxin deep into the subcellular tissue and applying a drop of collodion over the puncture to seal it. In this case, as in all cases, I did not use any massage after the injection to permit the absorption of the healing serum. All of my cases, with a few exceptions, were injected in the interscapular space, as practised by Professor Baginsky, and also endorsed by a great many others, chiefly Aronson, in Berlin.

On December 11th, the day following the injection, the temperature was

	Morning.			Evening.		
	Temperature. (Deg., F.)	Pulse.	Respiration.	Temperature. (Deg., F.)	Pulse.	Respiration.
December 11th	99.5	140	30	99	145	32
December 12th	100.2	130	26	101	124	25
December 13th	100.8	120	24	99.5	120	24
December 14th	90.5	124	24	98.5	108	22
December 15th	99	112	23	98.5	112	22
December 16th	100	108	22	100	114	22
December 17th	99	110	22	99	110	22
December 18th	98.5	102	22	....	...	..

On December 10th the child was injected by me. On December 16th Dr. Kessler wrote to me that the tonsils, pharynx, and uvula were free and clear of all visible membranes, also, that he noticed, a few days previous, the gradual melting away of the same. This child was discharged as cured on December 18th. Recovery complete. The local treatment consisted of antiseptics, strong stimulating diet; careful hygiene was also carried out. In this case a bacteriological examination of the pseudo-membranes was also made, and the report sent to Dr. Kessler showed the existence of Klebs-Loeffler bacilli, which corroborated his clinical diagnosis.

The following two cases were seen by me, in consultation with Dr. W. E. Bullard, in this city:

A child, male, four years of age, was attended by Dr. Bullard for a severe form of diphtheria. Plain visible pseudo-membranes could be seen in the pharynx, which appeared dark gray. There was a fetid smell of the breath, enlarged submaxillary glands. Dr. Bullard made a culture, sent it to the Board of Health, and received the report, showing Klebs-Loeffler bacilli. The child was so restless and hard to manage that the physician could not do anything with medication by mouth. The doctor decided to apply local applications, and even these were strenuously opposed. It remained then for Dr. Bullard to decide upon antitoxin, and the child was seen by me on December 26th, or about three days after the first appearance of the symptoms. The temperature was 99° F. The mother told us that the child had been ill a few days; had had fever, and had vomited on the day previous. The membrane, as first examined, covered the velum palati, both tonsils, and as much of the laryngeal wall as could be seen with the eye. Dr. Bullard prescribed a tincture of chloride of iron, ten drops every hour, but he is positive that the child received little or none of it. The patient continued to grow worse, the membranes were thicker and thicker, until the seventh day of the illness. When I first saw the child the temperature was subnormal, 97° F., and on the day following the injection the temperature was normal and rose until it reached 99° F., which was the highest it attained during the whole course of treatment. I injected 12 c.c. antitoxin, using ordinary antiseptic precaution, in the interscapular region, in the presence of Dr. Bullard. There was no reaction following the injection of the serum which could be ascribed to the serum itself. In the twenty-four hours following the injection Dr. Bullard noticed a red circle surrounding the membrane on the uvula. The redness increased as the membrane decreased. On January 2, 1895, which was the third day after the injection of the antitoxin, the membranes were almost invisible on the uvula and tonsils. The child's appetite improved in twelve hours after the first injection.

The second child in this family was taken ill on the same day I injected the first child, and for prophylactic reasons it was decided by Dr. Bullard and myself to inject 2 c.c. of antitoxin, to produce immunity if possible. Although no typical diphtheria could be proved, still the pharynx showed a slight milky coating, which looked suspicious. This child remained ill only about one day, and was well after that time; had no fever, and did not contract diphtheria. Still more interesting, however, in the same family, is the fact that the mother of these two children, who had been around nursing and looking after them, was taken sick with a mild infection of the throat, pain on swallowing, and what Dr. Bullard believed to be a typical diphtheritic infection. She also is well, and was cured in a few days.

The next case was attended by Dr. Krog, in this city. A child, two and one-half years of age, with a diagnosis of diphtheria and croupous laryngitis, stenosis, etc. I saw the child in consultation on January 8, 1895. At noon I found the following conditions: The child was cyanotic and had a pulse of 180; cold extremities; extreme dyspnœa. Although I was sent for to inject antitoxin, the urgency of the symptoms demanded prompt relief, which was given in the form of hot mustard foot-baths; internally, strong coffee and brandy and other excitants, besides a rapid intubation. The child's breathing was immediately relieved after the intubation, and when the child recovered from the reaction following the same, I then injected 20 c.c. antitoxin, using the ordinary antiseptic precautions, in the interscapular region. The dyspnœa was so much improved that the child immediately went to sleep. The temperature was 100° F.; pulse, 130, within one hour afterward. The appetite was good. I ordered raw scraped steak, buttermilk, and semi-solid nourishment as long as the tube was in place. The course of this child's disease was very protracted. The glands of the neck were extremely swollen, and the membranes seemed to disappear very slowly. A distinct improvement was first noticed two days, or about fifty hours, following the injection of the antitoxin. I allowed the cannula to remain five days, when Dr. Krog and myself agreed that the stenosis being so much improved, and the membranes not visible, appetite and sleep both normal, to extubate on January 11th. A careful examination of the urine, using Eschbach's albumin metre, showed five pro mille and a few epithelial and hyaline casts. A careful examination of the extremities showed no œdema of the body. This condition of nephritis lasted in all about eleven days, and also a small trachitis and cough remained, which I ascribed to the irritation and probable pressure caused by the tube, as nothing could be diagnosticated by an examination of the lungs. The child did not lose any flesh during the course of treatment, and the albumin disappeared gradually until the fourth week following the injection of the antitoxin, when the urine appeared normal. The cough also subsided, appetite returned, child slept well, and was discharged cured.

The most interesting portion is the bacteriological examination in this case. The first culture proved the presence of Klebs-Loeffler bacilli. The day on which we declared the child cured and the question of disinfection of the apartments came up, I made another culture, which again showed the presence of virulent

Klebs-Loeffler bacilli, and even seventeen days after I discharged the child as cured there still could be found Klebs-Loeffler bacilli by a bacteriological examination. In all five cultures were made, which proved the presence of Klebs-Loeffler bacilli. This, therefore, is a very important point, proving the necessity of the extremest care in the sick and the isolation of the healthy children, and especially the useless disinfection as practised to-day too early. It has been proved by a great many observers that a child should not be discharged as cured until really two distinct cultures were made on two different days, and both proved negative. The one should be made, if possible, by an officer of the Health Department, and the second should be made by the attending physician.

Dr. Ladinski was called, on November 9th, to a child about two years of age, and diagnosed tonsillar diphtheria. He sent a culture to the Health Department, which reported the presence of Klebs-Loeffler bacilli and diagnosed diphtheria. Dr. Ladinski gave the usual antipyretic and antiseptic treatment, using corrosive sublimate internally, until the child appeared to get worse. He next resorted to calomel fumigation, as recommemded by Dr. Dillon Brown in this city. The temperature rose in four hours from 102.2° to 103.6° F., and the child appeared very weakened. So I was sent for, in consultation, to use antitoxin. I injected 10 c.c. of antitoxin in the interscapular region on the midnight of November 21st. The temperature fell to 100.6° F. at 2.30 A.M., and was 101.5° F. at 4.30 A.M., and then fell slowly until eight o'clock the following evening, when the temperature registered 102.2° F. At eleven o'clock on the night of November 22d, the temperature was 99.6° F; therefore the temperature fell in this case in twenty-three hours from 103.6° to 99.6° F., without using any medication internally besides the injection of antitoxin. On Friday, the 23d, at four o'clock, in the afternoon, the temperature was normal and remained normal. The membranes which were visible previous to the injection had disappeared with the sinking of the temperature, and in the same way the glands at the angle of the jaw reduced in their size and slowly disappeared. The local treatment in this case was carefully followed out by Dr. Ladinski's orders, using a 1,000 to 2,000 sublimated solution on cotton swabs or by spray.

In this case, as in all other cases, we were indebted to the careful comments of the trained nurses in charge. The child remained well and had neither a complication of nephritis nor paralysis. The cases just cited have all of them been under five years of age. They were all cases in which we had recognized a severe diphtheria, and in which the prognosis was not only extremely grave, but in most of them the prognosis was fatal. The fact that the children were extremely weak, and had had different forms of treatment previously, did not seem to affect the action of the antitoxin, nor did it influence it in any way; it did not seem to exert any influence in the complications following the injection of the antitoxin whether treatment was or was not used before the injection of the serum. Besides the cases above cited, I have seen other severe and complicated cases in consultation with Dr. Romm, Dr. Waechter, Dr. Samuel M. Landsman, Dr. David Goldstein, Dr. Lazear, Dr. A. C. Carpenter, Dr. Stieglitz, Dr. Landes and so on, in all 225 cases. In 45 of these cases it was necessary to intubate; in 3 of these cases tracheotomy was performed. One case, in consultation with Dr. Goldstein, died through the carelessness of the nurse, and it is hoped that Dr. Goldstein will publish his own report of the same. In none of these cases was intubation or tracheotomy performed unless it was found absolutely necessary. In some cases an emetic was first tried to dislodge membranes and possibly relieve stenosis. In others ice-poultices, in the form of ice-bags on the neck, were used, and other palliative remedies. It is hardly necessary for me to cite other cases, having gone into detail with the last few, but I would rather speak of the indications necessary for the treatment of diphtheria with this new remedy.

If we consider that antitoxin is a product of the toxins of diphtheria injected into the horse, and that we use the blood-serum after an immunity has been produced in the horse, then we see that these toxins produce antitoxin and are only capable of healing diphtheria and really nothing but diphtheria. In one of his last reports Behring mentions the fact that he was prompted to produce antitoxin by watching the course of pneumonia. He noticed that nature will in a good, healthy individual, suffering with pneumonia, permit the same to have a temperature as high as 105° F. on one day, say at the crisis, and without any medication. Without any reason the temperature will suddenly drop to normal, proving what? Proving that nature has generated in the body certain antitoxins, which have certainly neutralized all the septic poisons generated by the toxins in the course of a pneumonia, and hence, the septic material being neutralized, the temperature returns to normal and the febrile process is at an end. It is easier, however, to write this on paper than to prove it on the living, and I will caution you, therefore, not to believe that antitoxin is a cure-all, but rather, that it is a remedy which has served me well and which has served the most prominent clinicians in Europe, and besides, has reduced the mortality in a great many instances from forty per cent. and fifty per cent. to fifteen per cent., and even lower. Considering also the fact that epidemics of diphtheria vary in different seasons, it is a very welcome remark to read Professor Baginsky's paper in the MEDICAL RECORD, October 6, 1894, and note that he expresses himself in the following terms: "That given our worst form of epidemic and our mildest form of epidemic, and the ordinary form of treatment as practised heretofore, the mortality was about thirty per cent., whereas since the introduction of the antitoxin the mortality sank as low as eleven per cent." This latter speaks volumes.

In the application of the remedy we must consider, therefore: 1. To apply the remedy as soon or as early in the disease as possible. 2. To inject a sufficient quantity. 3. Remember that the remedy given to us is absolutely harmless. 4. That the same can be used for prophylactic purposes by injecting the one-tenth part necessary for healing an acute case of diphtheria. 5. It is well to remark that although we use antitoxin the patient still requires local treatment of the infected places with a sublimated solution or other antiseptics; that the question of stimulants and hygienic and dietetic rules must be strictly carried out, and that, in a word, we must not expect healing wonders from this new remedy.

In thirty-six or forty-eight hours, at times, we should only look for the neutralization of the septic poisons absorbed in the body, and that therefore we can promise a great deal more in the commencement of the diphtheria by injecting a sufficient quantity, without further internal medical treatment. Emphasize, however, the extremest caution for hygienic and dietetic rules—if so, we must and will cure our case.

In order, however, to be sure that we are dealing with a case of diphtheria, which appears clinically so, it is necessary to prove the diagnosis by making a bacteriological culture of the same. We can, however, always safely treat a case as diphtheria that shows a membranous deposit on the pharynx, larynx, or tonsils or uvula, swollen glands, high temperature, or even low temperature, somnolence, and then wait for the result of a bacteriological culture to prove the diagnosis.

In Berlin a child is put into an observation pavilion and a culture for Klebs-Loeffler bacilli made immediately upon admission, and if the case looks clinically like diphtheria it receives at once its injection of antitoxin. If, however, the culture does not prove Klebs-

Loeffler bacilli the child is isolated and the treatment continued symptomatically and cultures again made; for how often has it happened, especially in the examination of newly formed pseudo-membranes, that no bacilli could be found, and how often can bacilli be found in older portions of the pseudo-membranes in almost a pure culture, so that we must also not forget that a technical error might be made in making cultures, and not be satisfied with one or two negative examinations. I saw a child with a severe form of septic diphtheria in which seven cultures on seven different days showed the absence of Klebs-Loeffler bacilli. This child died, and the post-mortem culture, two hours after death, was negative, and still no membranes involving larynx and trachea were present, as still no bacilli could be found. This shows that isolated cases may give us some trouble in verifying our clinical diagnosis. It is, therefore, perfectly proper to rely on the clinical diagnosis, as in the last case cited by me.

I was called to a child, about seven years of age, which had a severe pharyngeal, nasal, and tonsillar diphtheria, enormous infiltration on the throat and glands, not a very high temperature, extreme somnolence, fetor of the breath. The case was attended by Dr. Gengenbacher. In consultation, on November 29th, and after a careful examination, we decided that we were dealing with rather a severe form of septicæmia, and believing that antitoxin would do good in this case, I injected 10 c.c., *exitus lethalis*, after twenty hours. Had I known then what I know to-day of the value of antitoxin, I should not have injected that case, but would have warned the physician rather to use other remedies and not depend on antitoxin. To prove that, I was called in consultation, on December 3d, by Dr. N. S. Roberts to a severe form of septic diphtheria. I found the case to be the same as the clinical picture which I have given in the case of Dr. Gengenbacher. I decided not to inject this case, after consultation with Dr. Roberts, as it was really moribund and in the last stages of septic poisoning. The child was suffering from a mixture of scarlet fever and diphtheria. Another child, however, in the same family, which was two years of age, and which Dr. Roberts told me had been exposed to this infection, was injected by me in presence of the attending physician, with 2 c.c. of antitoxin for immunity purposes. Dr. Roberts wrote me that this child remained well and did not suffer any infection, proving the value of the immunity injection.

Contra-indications for the usage of antitoxin are: 1. Cases of mixed infection; cases of scarlet fever complicating diphtheria; cases of measles complicating diphtheria; cases of chicken-pox complicating diphtheria, and so on. 2. Cases that are moribund. 3. Cases that appear to be true septicæmia, where we have rather a result of the diphtheria than a real diphtheria to contend with. 4. I found that it was very important to make a careful urinary examination microscopically, and cases that showed a distinct evidence of casts and large quantities of albumin should not be injected with antitoxin.

I find, furthermore, that in a great many cases where casts appear in the urine, and large quantities of albumin, before injecting the antitoxin, that we frequently had quite some hæmaturia, bloody urine, as also severer symptoms, like swollen joints, swollen extremities, etc.

The eruptions which most commonly appear to follow the antitoxin have been varied. Some look like scarlet fever, some appear like measles, most of them look like erythema; seven cases looked like urticaria; nine cases showed purpura hæmorrhagica; where, however, these last purpura spots appeared it was found that coincident with these there was blood in the urine. I found these purpura spots chiefly surrounding the joints, on the face, and never did I find one in a case that received less than 10 c.c. of antitoxin, so that I was ready to believe that the greater the quantity of antitoxin injected, the more liable are we to have eruptions, especially of purpura. In one typical case in which we had purpura hæmorrhagica spots, there also appeared spots in the throat, and the gums looked like a typical case of scorbutus. Whether these eruptions are due to impurities of the antitoxin, or whether they are due to a previous disease of the horse and some impurity of its circulation, I do not know. It is, however, a positive fact that I have seen twenty-five cases of diphtheria injected with one kind of antitoxin, in which I did not have any exanthema whatsoever, and again, in another twenty-five vials of antitoxin injected, I seemed to have an eruption in almost every case, one eruption milder and others severer. These eruptions would appear and disappear and reappear when the first, second, and third injection of antitoxin were given, so that there could be no question that the coincidence of the eruption and the antitoxin injection was positive and that one was due to the other.

Finally, permit me to state that the choice of the seat of injection is entirely secondary to me, because I had injected the arm, I had injected the leg, I had injected the abdomen, but chose the interscapular region, because children do not see the needle, and I always could eventually lay a child on the knees of the nurse, face down. It appears to me to be the same as the choice of vaccination of the arm or leg, as practised to-day with cow virus.

I had brought over a small syringe containing 20 c.c., which was recommended to me by the kindness of Dr. Aronson in Berlin, and which was used by Professor Baginsky in the Children's Hospital in Berlin. I have had this syringe constructed through the courtesy of Mr. George Ermold, instrument-maker of this city. I am informed, however, that the firm of Schering & Glatz has imported the original syringe from its maker in Berlin. I should like to emphasize what has already been reported and published by me last October and November, that *5 c.c. of Aronson's healing serum will serve me, and has served me, as well as 10 c.c. of Behring's No. 2, and sometimes as well as Behring's No. 3. No. 1 solution of Behring is so weak for healing purposes that it should only be used, if at all, for immunity purposes.* When we think of the small quantity that can be injected by using a concentrated solution, as sold in this city, of Aronson's serum, it is wise in my opinion to use rather 5 c.c. than to be forced to inject 20 c.c., as the pressure of a larger quantity of fluid has in most of my cases made the children cry with pain for several days. Older children and adults described the pain as of a neuralgic character.

I have seen in all 225 cases in New York, in Brooklyn, and in Jersey City in consultation and private practice. I have reported in the *American Journal of the Medical Sciences*, January, 1895, 34 cases. In a great many of my cases I have injected two and three in one family; seven children for prophylaxis, besides injecting at times one, two, and three sick children for the curing of diphtheria. Several of my cases had been injected in the Children's Department of the German Poliklinik. One hundred and sixty-five cases were children under five years of age. I have also injected six adults. The other children were all over six years of age. Of these I have discharged as cured 191 cases in my own practice, and through the reports of the attending physicians in the various other cases, my mortality has been 34 cases, besides one accidental death, due to the carelessness of a trained nurse in a case in which tracheotomy was performed. Of these cases 68 showed distinct symptoms of nephritis, which could be proven microscopically. The importance, therefore, of a careful microscopic examination of the urine cannot be overdrawn. Besides the cases just cited of nephritis, 141 cases showed albumin in the urine; in these cases, however, we could not find any casts. In 64 cases hæmaturia appeared about thirty-six hours, in some forty-eight hours, following the injection of antitoxin,

and in which, I believe, we can ascribe the existence of the same to the injection of the antitoxin. It is, however, of the extremest importance to wait some time, until we can definitely prove whether this is a fact or not. In a given case, a strong boy, three years of age, with albumin in the urine 5 pro mille, according to Eschbach, the quantity of albumin increased to 9 pro mille twenty hours after the injection of 5 c.c. Aronson's antitoxin. In this case there were distinct symptoms of hæmaturia present. The symptoms, however, disappeared in two days after the injection, as also every symptom of blood. This was verified by a microscopical examination. Three days later I gave another injection of antitoxin, and again the albuminuria was increased and also the hematuria. Then a distinct eruption of purpura hæmorrhagica was visible. The eruption disappeared in five days. A strange observation was the fact that the eruption appeared much heavier and much thicker in the evening until midnight and disappeared toward morning. These symptoms were found in one distinct consignment of antitoxin, consisting of twenty-five bottles. Strange to say, the next consignment of twenty-five bottles, which arrived from Berlin three weeks later, did not give me any exanthemæ, resembling measles, urticaria, or scarlet fever, so much so that I was greatly impressed with the idea that possibly the eruptions in my previous case were due to some specific impurity traceable to the horse's blood or his system, and possibly the other consignment of antitoxin, which did not yield eruptions, may have been drawn of a healthier horse. The quantity to be injected is of very great importance. So I find that 5 c.c. of Aronson's antitoxin yielded just the same results as 10 and 12 c.c. of Behring's No. 2. This concentration of Aronson's antitoxin I regard as of very great value. This has been repeatedly pointed out by me in the MEDICAL RECORD—October 6, 1894, and later on, November 17, 1894, same journal.

Post-diphtheritic paralysis has been frequently observed by me during the course of antitoxin treatment. I have in all had twenty-one cases of facialis paralysis, and also paralysis of motion; paresis of the upper and lower extremities has also been observed by me. In all these forms of paralysis, however, there appeared some symptoms, and some are still to-day under treatment, although it is three months since the injection of antitoxin was given. I do not, therefore, believe that we can modify the course or the form of the paralysis occurring during diphtheria by injections of antitoxin. I do think, however, and I have seen cases that were injected early, that did have very mild forms of paralysis, so much so that it is possible that the antitoxin neutralizing the poison of the diphtheria absorbed in the system prevents, and probably modifies, the amount of septic matter absorbed, so that the toxins in the system do not affect the muscles and nerves as if they were not neutralized so early. The technique of the injection consists of—1. A careful sterilization of the skin of the patient to be injected at the seat of injection, the interscapular space, or the pectoralis region. Sterilization consists of washing of the skin with soap and warm water, then sponging the skin with a 1,000 to 2,000 sublimate solution. 2. The hands of the physician must be carefully and properly cleaned and rendered aseptic. 3. The syringe should be completely sterilized by boiling fifteen minutes in a soda solution. The needle should be dipped in alcohol, followed by a two per cent. solution of carbolic acid. 4. It is necessary to inject slowly; at the same time to have the proper quantity of serum drawn into the barrel of the syringe, so that no time is lost. The needle should be pushed into the deep cellular tissue, at least two inches in a semi-horizontal position. 5. Massage of the fluid injected with the skin should not be practised; finally, I should apply a very small pledget of absorbent cotton over the injected space, and the oozing of a small quantity of serum makes a film which completely prevents the entrance of septic material. The injected spot can also be sealed by dropping collodion over it.

The absorption of the antitoxin takes usually from one-half to one hour. At times I have seen a swelling produced by the injection of 5 or sometimes 10 c.c. of antitoxin remain for fifteen and even eighteen hours in one case. This is, however, rare. In other cases I can remember that the swelling disappeared within twenty minutes.

I have previously mentioned the fact that I refused to inject a case after consultation with Dr. Roberts. The same was true, later on, in consultation with Dr. Shulman, in which case the child was so moribund that we believed it useless. Both children died very soon afterward, and I have therefore reduced my mortality somewhat by not injecting these hopeless cases of septicæmia. Finally, I desire to state that my mortality has been 35 in 225 cases treated; 22 cases were under five years of age; 16 of the latter were under three years. My mortality has, therefore, been equivalent to $15\frac{5}{9}$ per cent., although my percentage of cures in the first 34 cases reported was $5\frac{8}{10}$ per cent. The high death-rate given by me is far above what has been given in Berlin, the Children's Hospital, and in several other hospitals abroad. This can easily be explained by the fact that in the majority of cases in which I was called in consultation to use antitoxin, it was used as a last resort only, and therefore the majority of cases were looked upon as hopeless. I took chances of injecting a great many cases in which we considered a grave prognosis, and therefore have attained the results specified above.

In conclusion, I desire to state that antitoxin should be used early, and believe that if the rules given above be carefully carried out, it is a safe remedy and can cure every case of diphtheria seen early; and even the most malignant cases should be injected, because I have seen moribund cases that were considered absolutely beyond medical control get well. I again state, however, that I do not believe it a cure-all, but believe it to be the best known remedy for the treatment of diphtheria in use to-day.

187 SECOND AVENUE.

ANTITOXIN IN DIPHTHERIA.

BY CYRUS EDSON, M.D.,

COMMISSIONER OF HEALTH FOR THE STATE AND CITY OF NEW YORK.

I HAVE recently had an unusually good opportunity to observe the use of antitoxin in the treatment of diphtheria, in two cases, occurring in my own family.

CASE I.—On Sunday, March 3d, a boy, aged seven, was attacked with vomiting; there was slight elevation of temperature, and his throat was slightly congested, but in no respect was there anything characteristic of diphtheria. On Monday morning a thin, grayish membrane covered the soft palate, the tonsils, and the pharynx. A culture was at once taken, and without waiting for the result of its examination, 6 c.c. of the antitoxin serum was administered at 3 P.M. of that day. This, it will be seen, was within thirty-six hours of the attack. The serum used was prepared in the laboratory of the New York Health Department, and was unusually strong; $\frac{1}{2000}$ c.c. of it having prevented the death of a guinea-pig weighing 250 gm., which had received an amount equivalent to ten fatal doses of diphtheria toxin. It will be remembered the preparation known as Behring's No. 3 (the strongest of Behring's antitoxins) is considerably weaker than this serum used, since it requires a dose of $\frac{1}{1500}$ to $\frac{1}{1000}$ c.c. to neutralize "ten times a fatal dose to a 250 gm. pig."

The temperature on Monday at 8 P.M. was 104° F.; the membrane appeared thick, white, and of a leathery consistency, almost completely covering the pharynx; breathing was rapid and difficult. In a very large ex-

perience with the disease I have never seen a more profuse exudation nor one of more malignant aspect. This view, as taken by me, was not due to the natural anxiety of a father, for Dr. H. M. Biggs, to whom the medical direction of the case was entrusted, concurred with me in the opinion.

On Tuesday morning the result of a culture showed Loeffler bacilli; temperature at 8 A.M., 103⅗° F.; cervical glands much enlarged and inflamed. The circumference of the neck was very much increased, and over the enlarged glands the skin was red. Eleven cubic centimetres of the same serum was injected at 9 A.M. On Tuesday night, 8 P.M., temperature, 102⅗° F.; the membrane was detached along its free margin and a considerable portion of it was cast off. On Wednesday, 8 A.M., temperature, 100° F.: the membrane was partly cast off, though a large, loose mass was still to be seen in the pharynx; the respiration was not much impeded, nor was it so rapid. The throat was sprayed for the first time with Dobell's solution, and this was continued during the waking hours at intervals of every two hours. This, with the exception of four grains of gray powder, given on Wednesday and Friday nights, was the only treatment in addition to the serum. On Thursday, 8 A.M., temperature, 98⅘° F.; the membrane was nearly all gone, small granular spots of it only appearing over the tonsils (which were congenitally large) and over the posterior walls of the pharynx; the appetite on Thursday returned, for prior to this time during the course of the disease it had been difficult to induce the child to take milk, which was the only nourishment. On Friday, temperature, 8 A.M., 99⅖° F.; 8 P.M., 100⅕° F.; appetite good, membrane entirely disappeared. On Saturday, 8 A.M., temperature, 99⅕° F.; 8 P.M., 100° F.; throat normal, glands almost so; no redness of skin. On Sunday, temperature, 8 A.M., 98⅖° F.; the afternoon temperature was not taken, but it appeared to be normal; the appetite was ravenous and the child could with difficulty be kept in bed, as he asserted he was well and had been for some time. He did not seem to have lost flesh, nor to have been much weakened by his illness. He is an unusually robust child.

Case II.—A girl, aged nine, also remarkably robust, but with extremely large tonsils and a very nervous temperament, was taken sick with sore throat on Tuesday morning, before the report from the culture taken from the boy's throat showed positively his disease was diphtheria. Within three hours, however, subsequent to the visible commencement of the attack she received 6 c.c. of the same serum that had been administered to the boy. Temperature, Tuesday night, 104° F.; throat much congested but no membrane, and the culture taken showed the presence of suspicious bacilli, the report from this culture being received Wednesday morning. On Wednesday, 8 A.M., temperature, 102½° F.; patches of grayish exudate appeared over both tonsils, but this was not sufficient to entirely cover them; pharynx and uvula much inflamed. Six cubic centimetres of the serum were again administered at 9 A.M. The child was much terrified by the method of administration and had to be forcibly held. Temperature, 6 P.M., 104⅖° F. This high temperature was accompanied by a slight delirium, and was attributed to the effect on the nervous system of the struggle and fright incident to giving the antitoxin. By the advice of Dr. Biggs a single dose of ten grains of sodium bromide was given, and two drachms of whiskey administered every three hours. Within two hours and a half after the administration of the sodium bromide the temperature dropped to 100° F. On Friday, temperature, 8 A.M., 99⅖° F.; 8 P.M., 99⅘° F. Saturday, temperature, 8 A.M., 99° F.; 8 P.M., 99⅕° F. The child appeared well and extremely anxious to get up. During the course of the disease this child's throat was frequently sprayed with Dobell's solution. The injections of the serum in both cases were made in the abdominal region. Beyond the slight point where the needle entered the skin nothing is visible to show the site of any of the injections.

To a girl of twelve years, a sister of the children treated, 2½ c.c. of the same serum was administered for preventive purposes. Notwithstanding the fact that she was closely exposed, has a sensitive throat, with hypertrophy of the tonsils, and is extremely subject to tonsillitis, she escaped infection, but on the seventh day developed urticaria, which at first was localized over the site of the injection. The eruption covered an oval spot three by four inches, but did not extend or appear elsewhere until the ninth day, when a number of shotty papules, very closely resembling chicken-pox, but not proceeding to vesiculation, covered the dorsal aspect of the arms and hands, the chest, abdomen, and lower extremities.

The rash was most profuse over the arms and legs, and the itching caused by it was a very distressing symptom. The papules lost their shotty feel after twenty-four hours and spread by increasing their diameter until they coalesced and covered the extremities almost uniformly, leaving little streaks of white skin visible in places. On the third day after the appearance of the rash it began to fade, and by the evening of the fourth day it had totally disappeared. The temperature just preceding the appearance of the rash was considerably elevated.

During the outbreak the temperatures were as follows:

Day.	A.M. Degrees, Fah.	P.M. Degrees, Fah.	Day.	A.M. Degrees, Fah.	P.M. Degrees, Fah.
1	101⅕	102	3	99	99
2	99	101	4	Normal.	Normal.

On the eighth day after the injection the younger girl suffered from a profuse general urticaria. The eruption was intense and confluent, closely resembling the eruption of measles and involving the conjunctiva and mucous membrane of the mouth and palate. The itching and discomfort were so great that bromide and camphorated tincture of opium had to be given. The rash was preceded by a rise in temperature and persisted for five days. After the second day the eruption was much better at night, disappearing except in a few isolated spots, but reappearing after eating breakfast the following morning. During the middle of the day it appeared to be at its height. The temperatures taken night and morning were as follows:

	Degrees, Fah. A.M.	Degrees, Fah. P.M.
1st day of eruption	103⅕	103
2d day of eruption	102⅖	102⅗
3d day of eruption	101½	102
4th day of eruption	100	102⅗
5th day of eruption	99⅖	100½
6th day (eruption disappeared)	100⅕	103⅖
7th day, normal	99	Not taken.

Vaseline containing four per cent. carbolic acid appeared, in the case of the younger girl, to best allay the itching. In the case of the older girl, however, a solution of one ounce sodium benzoate in a pint of glycerine was made, and this being mixed with hot water in equal parts and used as a wash, seemed to give the most relief. The boy, who received the largest dose of the serum, and had the most profuse diphtheria exudate, did not, however, develop any urticaria until the seventeenth day after receiving the serum. Just preceding the appearance of the rash he seemed languid and complained of feeling tired. His temperature taken showed a rise to 102⅕° F. During the course of the day a number of wheals appeared on his arms, legs, and face. The diameter of these blotches was from one inch to two inches. The patches were isolated and gave rise to intense itching, which was relieved by a four per cent. carbolated vaseline. The temperature at night had fallen to 101° F., and the following morning was normal. The rash disappeared within six hours of its appearance, and did not again appear.

The two girls did not have at any time during the course of the disease, or afterward, any albuminuria, though the urine was frequently examined. The urine of the boy, however, on the third day after the attack was found to contain a trace of albumin, which disappeared about the sixth day.

A study of this eruption is very interesting. The cases treated by antitoxin at Willard Parker Hospital have developed it in comparatively few instances. Dr. Somerset, the resident physician, has reported the following facts concerning it :

Of 117 cases treated with antitoxin in the Willard Parker Hospital, 12 had an eruption which appeared between the eighth and twelfth days. Of these 12, the character of 4 was erythematous, somewhat resembling measles in appearance, distributed principally on the extremities, and exclusively so in 2 cases. These 4 cases were differentiated from measles by the irregular distribution of the eruption, the absence of coryza, conjunctivitis, and the characteristic measles temperature. Of the remaining 8, 5 were urticarial. The distribution of the eruption was irregular, the wheals varying in size, but seeming to be larger in the vicinity of the site of the injection, where they first appeared in 3 of the 5 cases. Most of the wheals had extensive peripheral erythema. The other 3 cases presented a distinct blush, irregularly distributed in areas of varying size. These areas were scarlatinal in appearance, but the distribution, tongue, and temperature were in nowise characteristic of scarlet fever. None of these rashes lasted longer than thirty-six hours, but in the urticarial forms they would disappear and again reappear, the alternations occurring perhaps three or four times in a single case. The eruptions seemed to occasion no inconvenience nor discomfort, and received no treatment other than occasional washing with some simple lotion. The temperatures were very irregular, and were usually highest before the rash appeared, but were in some cases highest during the eruption or immediately after its disappearance. Four of the five urticarial rashes occurred in cases receiving antitoxin from one particular horse, whose serum would thus seem to be more likely to cause an eruption than that from the other animals.

It will be seen there is a very distinct period of incubation after the administration of the serum and before the appearance of the urticaria. This period may be put at from five to seventeen days, and it shows, in my opinion, the eruption is not due primarily and directly to anything contained in the serum, *but rather to the action of the serum on the system of the patient ; or perhaps to the development in the blood of the patient of some pathogenic substance through this action. To effect this action, or, rather, to effect this change in the system of the patient, requires the time which elapses during the period of incubation.* It is evident that not every person is susceptible to this effect of diphtheria antitoxin, or that the toxin of diphtheria is an antidote to the urticarial effect of the antitoxin. Time and a careful study of a great number of cases will alone demonstrate which, if either, of these two hypotheses is correct. The normal horse serum may have the property of causing the eruption in susceptible persons.

Experiments are at present being conducted in the Health Department Laboratory, with a view of ascertaining the truth or falsity of this theory. It may be, however, I think, safely assumed that the eruption is a local lesion of a general disease, of which the serum is the cause. This seems to be proved by the distinct period of incubation and the rise in temperature, which, I think, will be found more or less characteristic in the majority of cases where the temperatures are carefully recorded.

Concerning the therapeutic action of antitoxin there is much conjecture. The agent does not act at once like drugs administered hypodermically, but requires a very distinct and somewhat prolonged period of time to do its work. This period varies from ten to twenty-four hours, and makes it essential that the remedy should be given early in the attack to effect its object.

The theories advanced, when antitoxin was first used, and which seemed to be the most tenable from a bacteriological stand-point, were : the immune serum sufficiently reinforced the natural resistance to the disease to turn the balance in favor of a cure, and that the blood of the immunized horse contained a sufficiency of something that neutralized the poison of diphtheria as an alkali neutralizes an acid. These theories do not appear to be correct, for if they were, the action would follow the administration more promptly. It seems to me more probable that serum acts through the changes it effects in the blood itself, and that it requires time to bring about these changes. Whether it is that these changes are chemical and are due directly to the effect of the serum on the blood itself, or that they are brought about through cell stimulation, or that they are due to the development in the blood of some new substance, is not in the least apparent.

It is interesting to study the mortality among cases of diphtheria treated with antitoxin at Willard Parker Hospital, since January 1 to March 10, 1895. The total number of cases treated was 117 ; the total number of deaths 27 ; the per cent. of mortality, twenty-three ; per cent. of mortality for corresponding period of 1894, thirty-three. During January the antitoxin used was very weak, requiring about $\frac{1}{100}$ c.c. to protect a guinea-pig weighing 250 gm. against an amount of toxin equivalent to ten fatal doses. This is about the strength of the solutions used for immunizing purposes. Of the 117 cases above named, 46 occurred during the month of January and the number of deaths was 13. The per cent. of mortality, therefore, for January was twenty-eight plus. January 31st to March 10th the number of cases treated was 71, the number of deaths 14, and the per cent. of mortality nineteen. The serum used during this period was considerably stronger, the immunizing dose for guinea-pigs being from $\frac{1}{100}$ to $\frac{1}{200}$ c.c.

The number of cases of croup since February 1st at Willard Parker Hospital was 30, the number of deaths since February 1st 10 ; per cent. of mortality $33\frac{1}{3}$; and the croup mortality for 1894 was fifty per cent.

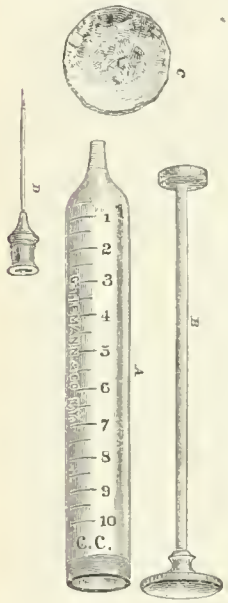
The number of operative cases of croup since January 1st was 22 ; the per cent. of mortality among these cases forty-five ; per cent. of mortality for 1894, eighty. The average number of days that the diphtheria cases were sick before admision and administration of antitoxin was, in the fatal cases, $5\frac{1}{10}$ days.

Week ending—	Cases.		Total.	Deaths.		Total.	Percentage deaths to cases.
	Diphtheria.	Croup.		Diphtheria.	Croup.		
January 6, 1894....	210	9		59	16		
January 13, 1894....	175	13		63	12		
January 20, 1894....	195	16		68	18		
January 27, 1894....	106	8		69	12		
			732			317	$43^{37}/_{100}$
February 3, 1894...	171	15		58	13		
February 10, 1894...	173	10		59	13		
February 17, 1894...	122	13		47	13		
February 24, 1894...	76	20		58	15		
			700			276	$39^{41}/_{100}$
January 5, 1895....	194	15		46	10		
January 12, 1895....	200	14		56	11		
January 19, 1895....	155	13		33	12		
January 26, 1895 ...	205	7		34	5		
			803			207	$25^{77}/_{100}$
February 2, 1895...	159	10		33	5		
February 9, 1895..	150	16		39	10		
February 16, 1895...	170	7		29	6		
February 23, 1895 ..	176	12		43	6		
			700			171	$24^{43}/_{100}$

The above table shows the cases of, and deaths from, diphtheria, occurring in New York City from January 5, 1895, to February 23, 1895, and for a cor-

responding period in 1894. A very marked diminution in the death percentage from diphtheria is apparent. That the diminution is not greater, is probably due to the fact that most of the serum available in January and during a part of February was weak and was not generally used. The mortality for March thus far is much lower.

In connection with the subject I would like to call attention to a new antitoxin syringe made by Tiemann & Co., after my design, and illustrated by the accompanying cut, which does not, I think, have any of the objectionable features of the ordinary syringe. The difficulty of cleansing the ordinary syringe is very great, and is due to the packing of the piston, which is generally of leather, and to the leather washers used to make the end of the barrel air-tight. Koch's syringe is really the only thoroughly good syringe from the stand-point of cleanliness, *i.e.*, ease of sterilization, but the instrument is difficult to handle and is liable to inject air with the serum. My syringe consists simply of a glass barrel (A) graduated in c.c., containing 10 c.c., open at one end and ground to a fitting at the other.



The ground end fits a needle (D) having a hard-rubber shoulder. The piston (B) is in one piece, the plunger extremity being a little smaller than the diameter of the barrel of the syringe. A disk of rubber (C) or tightly woven cloth of suitable thickness is placed over the open end of the syringe and the plunger inserted. The rubber, which may be cut from an ordinary rubber bandage, engages the end of the piston so as to form when wet a water-tight cushion which is operated just as is an ordinary hypodermic syringe. Before using the syringe the rubber and the entire syringe should be sterilized by means of hot water. I have also had Messrs. Tieman apply this principle to the ordinary hypodermic syringe, and the result is extremely satisfactory.

A metallic case or box is provided to hold the syringe and disks. The ordinary velvet-lined syringe case is an abomination, and should never be used in connection with any hypodermic syringe, still less with any syringe used for the administration of antitoxin. The case for the syringe should be as easily disinfected as the syringe itself. The wooden cases now generally provided for antitoxin syringes cannot be sterilized by means of heat, which in this connection is the only perfect disinfectant.

An instructive paper might be written on the subject of the introduction of antitoxin in the United States. Such a paper would illustrate forcibly the great interest taken by the laity in medical matters, and their appreciation of the valuable discovery in question. It was this interest and appreciation that made it possible for the Board of Health to obtain the necessary appropriations to extend the facilities of its bacteriological laboratory so as to produce the serum, and that caused the *New York Herald* to give the project such effective aid by its support and the large sum of money it collected through popular subscription. The outcome has been the rapid production of antitoxin, so that at the present writing the Board of Health can easily supply the State of New York from its surplus of serum, with sufficient to treat all the cases of diphtheria that occur during the ordinary prevalence of the disease. Much of this serum is equal to the excellent preparation known as "Behring's No. 3," and some of it is even stronger and better. As I have stated in another part of this paper, Behring's preparation No. 3 requires $\frac{1}{1300}$ to $\frac{1}{1600}$ c.c. to immunize a guinea-pig weighing 250 gm. against ten times a fatal dose of diphtheria toxin, while one of our immunized horses furnishes a serum which, according to the last test made of it, was sufficient in a quantity of $\frac{1}{2200}$ c.c. to immunize a guinea-pig against ten times the fatal dose of diphtheria antitoxin. Expressed in antitoxin units this statement would be as follows:

	Antitoxin normal units.
20 c.c. Behring's No. 3 contains	2,600 to 3,200
20 c.c. Board of Health's strongest serum contains	4,400

The full antitoxin strength that the serum of the horse can be made to develop varies in different animals. The animal which produced the serum to which I have alluded has developed an extraordinary degree of immunity.

The number of immunized animals at present in the Health Department Laboratory stables is thirty. The amount of antitoxin capable of being produced by them is about forty thousand c.c. per month.

I desire to place on record here my appreciation of the services of Dr. Hermann M. Biggs, of the Health Department, especially in connection with the production of antitoxin in this country. By Dr. Biggs's request the Board of Health detailed him, in May, 1894, to study the subject in the laboratories abroad. Shortly after his arrival in Berlin he wrote letters fully describing the new remedy and its great promise. He also wrote directions to his assistant, Dr. William H. Park, to prepare the necessary toxin, so as to be ready to begin at once, on his arrival, to administer it to animals. To Dr. Biggs more than to any other man is due the early introduction of antitoxin into the United States.

MODERN TREATMENT OF LARYNGEAL AND PULMONARY TUBERCULOSIS.[1]

By CARL VON RUCK, M.D.,

ASHEVILLE, N. C.

In presenting some of my observations in the treatment of pulmonary tuberculosis I may say that, in my experience, the general management of the patient has proven itself of such importance that, without its correct application, there is little, if any, prospect for success. No matter what measures we may otherwise employ, the faulty conduct of the patient, his unhygienic environment, or his dietetic errors cause him to relapse so frequently from any benefit our therapeutic measures may have brought about, that the course of the disease is, as a rule, a downward one, in spite of all the remedies which we employ.

The general management must therefore be considered the foundation for the superstructure of symptomatic and direct treatment, and the fundamental principle which in its application should govern us at all times and under all circumstances is, "To secure and maintain the highest possible degree of general and local nutrition." In order to secure it in all directions we must not only have enough of good, well-cooked food, but we need also good digestion, assimilation, oxidation, and excretion, which to obtain and to maintain we must look into our patient's whole mode of life, and control it wherever necessary; we must learn his good and bad habits, and his tendencies to errors; examine into the healthfulness and function of all the rest of his organs and correct everything that is possible toward getting the greatest amount of vitality and physical vigor, by which we increase the inherent forces of the organism for successful resistance to the disease. To this end we should not only understand the pathology and course of pulmonary tuberculosis, but also general and special pathology and physiology in their relation and effects to health and disease.

[1] Read by invitation before the County Medical Association of New York, March 18, 1895.

The physician who can bring the greatest amount of such special and general knowledge to his case, must of necessity be the most successful (providing he also makes painstaking application of the same). Failure is practically certain for him who does not appreciate the great influences exerted by the individual physical condition of the patient, especially through the organs of circulation, digestion, assimilation, and excretion, upon disease in general, and upon the course of pulmonary tuberculosis in particular.

In considering these influences it would be next to impossible to anticipate every abnormal condition an individual patient may present, but the more important and most frequent indications I will endeavor to outline by a short review of my own practice.

Excepting cases in the earliest stages, when I take charge of a patient I order rest in bed, stopping all previous medication, and observe the course of the disease for a day or two, during which I make such changes in diet and the patient's mode of life as seem to be indicated. I also look after the condition of the skin ; begin with baths or cold rubbing, examine the urine, the sputum, the blood—obtain a record of the temperature, pulse, and respiration ; and, with a full physical examination after having taken the previous history, I am now ready to consider the evidence before me and to form an opinion as to what my patient's condition really is. The future management depends entirely upon what I have found. If the patient is practically free from fever, or if fever is absent for the greater part of the day, constant confinement in bed would not only be unnecessary, but would otherwise interfere with the patient's best interests. According to his strength, he is allowed to be up during the hours when the temperature is not elevated, and must be out of doors, either at rest there, or taking such exercise as his physical condition would warrant to risk, without incurring any sense of fatigue or shortness of breath. The amount of the exercise is controlled by its effect upon the circulation and upon the fever, and an increase is only allowed cautiously and gradually. Unless the digestive organs are deranged the patient is allowed a liberal mixed diet, which is supplemented by milk between the meals, if necessary. If the temperature record at any time shows elevation above 100° F. the patient must go to bed and remain there until the temperature has declined, and he must anticipate the probable rise on the following day by retiring at least one hour earlier. During fever hours the diet is light, the feeding more frequent. Hearty meals of meats, eggs, and coarser vegetables, if given shortly before, or during fever, are very apt to increase it, or invite its recurrence. The patient receives a cold rub every day before rising ; but subnormal temperatures require caution in this respect, and it is best to wait with the bath until a normal temperature is reached, the patient remaining in bed until then.

If the case is of an acute character, or if complications occur, with continuous fever, every attempt to treat such a case without absolute rest in bed interferes with the arrestment of acute symptoms, and, as a rule, defeats the chances for improvement or recovery. In such cases we apply massage or electricity, or both, and substitute therewith the desirable exercise, while in suitable weather we bring the bed near the windows for the direct exposure of the patient to sunlight and out-of-door air. Absolute rest in bed is also imperative during complications like pneumonia, pleurisy, or hemorrhage, and they must have entirely subsided before the patient is allowed to be up and take exercise.

In all other ways the general management is constantly endeavoring to keep the patient from all harmful influences on the one hand, while taking advantage of everything, little as it may appear, toward keeping him in the best possible condition, on the other. Exercise, amusements, or light occupation, reading, mental states, clothing, position in sitting or reclining, partial or complete exposure to sudden variations of temperature, or to draughts and the like, are all important matters for watchfulness and proper advice ; and instead of relaxing our vigilance when the patient is improving we need to double it, for then he is willing to take more chances than he would have taken at a time when his symptoms made him aware of his danger. All this means, however, that the patient must be under continuous observation, and a single misstep or deviation from the proper course can be followed by relapse which it may take weeks, and months, to overcome, or which, indeed, may prove itself an irretrievable loss.

Near relatives are seldom reliable enough to so take charge of a patient, especially if the case is a severe one ; they are only too apt to regard the patient's desires and entreaties in a more or less hazardous direction, and it is difficult for them to say "no" in matters the importance of which they, as well as the patient, are apt to underestimate. Thus the ideal management is extremely difficult in private practice, and by no means an easy task in a special institution.

By the time a patient has learned from bitter experience all that may prove injurious, he is, as a rule, in an advanced stage, and it takes character, will-power, and self-control of a high degree for a patient to make a smooth and uninterrupted recovery, even when he comes in an early stage. The physician who, however, can have personal control, who can see and observe his patient at all times, whose directions are rigidly complied with by his assistants, and who can so circumstance his patient that harmful influences are practically excluded, has a great advantage, and he gains much valuable experience. Under such care arrest, more or less permanent, of pulmonary tuberculosis may occur without resort to any other treatment, especially in the early and uncomplicated stage of the disease.

In the symptomatic treatment of pulmonary tuberculosis almost any therapeutic agent may find rational employment at one time or another during its course of months and years. The limits of this paper forbid their consideration in detail, but so far as we may employ drug remedies, it means often that we are to choose between two evils, and we must, therefore, have good reason to believe that the benefits which experience justifies us in expecting will result, without incidental drug effects, which would prove in the end that our interference has done more harm than good. Upon such consideration rests the symptomatic treatment of all disease, and tuberculosis is no exception.

Under the head of general management I should also speak of climatic treatment, which, of all our means, is one of the most important for the arrestment of phthisis. There is, however, nothing specific in climate any more than there is in water or food. Climate is everywhere, and the difference in the purity of the air or in its density, in dryness of the soil, or in temperature, are relative matters, between one locality and another. Clinical benefits result altogether from its influence upon nutrition ; and in so far as elevation is also a factor, from its influence upon the circulation, the improvement of which is again a matter of better nutritive processes, both local and general.

The employment of climate means that we seek pure air, as free as may be from micro-organisms, from dust and from deleterious emanations of decomposing organic matter ; air which is sufficiently dry so that the functions of the skin are under most favorable conditions, in a locality which, by its elevation, improves the circulation, and at which the conditions of temperature favor an out of-door life with the resultant better appetite and oxygenation, while with the increased solar effect at elevated places, under a clear sky, we hope to influence the usually deteriorated blood state for the better.

That all of these conditions are highly desirable for the phthisical patient I need not dwell upon, nor is it

necessary to seek for mysterious specific effects when the explanation of its benefit through nutritive influence is so apparent. Climatic treatment is thus justified in every respect, but it is a serious error to believe that when the best is not within our reach that we are justified in ignoring its rational use in less favorable localities.

If I were treating my patients in New York City, instead of Asheville, N.C., I should still make the climatic treatment a most important part in their general management, and it would here, as there, begin with proper and judicious ventilation of house and room. I would take advantage of the best air I could get, and of every hour of sunshine nature would vouchsafe, while I would protect my patients against unfavorable influences from changes of weather, etc. In the open country still better results would follow, and its good influence through the purer air and the greater out-of-door life has been a matter of common observation in places that in nowise can pretend to compare with the climatic conditions of celebrated health resorts. In the choice of the latter for phthisical patients I can add little to what has already been stated by Dr. Gleitsmann, and only call your attention to the fact that as far as elevation is concerned a golden mean offers every advantage and none of the disadvantages of sea-level and the high-altitude localities. In the latter the effect of the greatly diminished air-pressure upon the circulation of patients at all beyond the earliest stages has often caused serious disaster, and the extremes of temperature which increase with the elevation, as well as the excessive dryness, are often serious hindrances, rather than benefits for the patient's best welfare. But whatever the climate may be, it cannot protect the patient from errors in his general conduct, and an ideal general management must ever continue to be the most potent factor in the final results obtained.

From these considerations it naturally follows that comparatively few patients are treated under ideal conditions for their recovery. The insufficiency is attested by the enormous mortality which we witness in pulmonary tuberculosis, and the benefit of such care is shown by the good results obtained in special closed institutions, particularly in such as have the advantages of a favorable climate also. At the very best, however, the arrestment of the disease is often only temporary, the cures are few, and take a long time to accomplish. In no case can we be sure for years to come that the disease is really eradicated, and the possession of a specific germicidal remedy is the desire of all who have to treat tubercular patients.

Hoping so much from the use of tuberculin after observing the involution and disappearance of the tubercular tissue and of the specific germs in the animal experiment, the despair which took possession of us when we realized that, owing to the toxic properties of the remedy, a specific for human tuberculosis was yet a matter of the future, is still keenly felt by all of us. Most physicians failed on that account to take advantage of what good there was in the remedy from its use in well-selected cases, in minute, safe doses, and they are now more sceptical than ever as to the possibility of obtaining a safe and true specific germicide. Such a pessimistic position is certainly unjustifiable. On the contrary, the successful animal experiments, as well as the good effects of tuberculin in a great number of well-observed cases of pulmonary tuberculosis still justify the greatest hope for the future.

I am not at all prepared to state to you to-night that this hope has been entirely realized, but I am very certain that an important step forward has been taken. Indeed, so far as I have been able to observe from clinical evidence and animal experiment, it appears that the germicidal part of tuberculin is now successfully separated in a substance resembling in its chemical reaction a deuter-pepton, which can be obtained from tuberculin or from the culture-fluid of the tubercle bacillus. With this substance Professor Klebs has made numerous experiments upon animals, and its apparent safety and the success claimed by him and others in its clinical use upon the human subject also, caused me, over a year ago, to make use of it, first in a few of my causes in which tuberculin was not tolerated even in minute doses.

Professor Klebs found that the use of this remedy is also followed by involution of the tubercular tissue and by the disappearance of the specific germ in tubercular guinea-pigs, the same as he had previously observed it to occur under the use of the crude tuberculin from like doses; he also found that guinea-pigs can bear much larger doses of the remedy than of tuberculin, one-half cubic centimetre of the latter killing such an animal, as a rule, within twenty-four hours, while several cubic centimetres of the purified substance cause no material disturbance in its health. The toxic substances which he separated from tuberculin produced the poisonous effect of the latter, and seemed to exert no curative influence when given in doses under which tuberculin caused the recovery of the pig.

I am at this time repeating these experiments, and as far as I have gone, I find the claims of Professor Klebs to be borne out by my results. This would prove that when this substance, now called "antiphthisin" is separated from tuberculin, the latter loses its curative influence upon guinea-pigs, and acts as a poison only, and also, that antiphthisin represents the curative properties of tuberculin, since under its use guinea-pigs show involution of the tuberculin tissue, outlive the control animals for many months, increase in weight, and recover entirely when the treatment is sufficiently active and applied for a sufficient length of time. It further shows that antiphthisin is non-poisonous in doses much larger than required of tuberculin to cause the death of an animal in twenty-four hours, all of which is certainly an excellent showing for the remedy so far as we deal with guinea-pigs, small animals in which death occurs at an early period from pure non-complicated tubercular disease.

In the treatment of human tuberculosis, while the animal experiment is of great value, it is not justifiable to assume that the same result would necessarily follow; first, because human tuberculosis follows, as a rule, a much slower course, the tubercular disease having existed perhaps for months, or even years, before distinct symptoms of its presence make their appearance; and we cannot hope to apply the remedy a short definite time after infection. It is only exceptionally that we have opportunity to treat our patients before caseation, fibroid changes, and other effects have been produced.

To get at all analogous conditions for comparison we must expect to find them in cases of acute miliary tuberculosis, but even there it is probable that the general infection had its source in some degenerate gland or local focus from which the germs became liberated.

If antiphthisin is a true specific germicide, we can only hope to influence the specific germ by its use, but we cannot expect to reach it except in living tubercular tissue, and its effect under the same dose must be in proportion to the vascularity of the part. In recent tubercular eruption in the lung the remedy should therefore give us the best results, while a cheesy degenerated mass, or a fibroid nodule, would remain entirely uninfluenced. Dead or necrosed tissue represents a foreign body, which, as well as fibroid changes or formed cavities, are results of tuberculosis, and cannot be made to disappear from the use of a germicidal remedy which can only remove the cause.

The coagulation of the protoplasm in the still living cells of tubercular tissue is caused by the specific germ or by its products; under the removal of the cause such cells again return to their normal condition, and Professor Klebs has shown this to occur under the use

both of tuberculin and of antiphthisin. This is all we can hope from the most perfect germicide.

The destruction of the bacillus of tuberculosis upon open surfaces, therefore upon the surface of cavities and localities where necrosis has already occurred, is necessarily more difficult, because under such conditions the blood cannot exert its germicidal properties, and at most but feebly upon the slightly vascular base, while the growth of the germ upon surfaces to which the air has free access is more rapid and luxuriant.

I cannot here follow the possibilities and limitations of a germicide for the bacillus of tuberculosis acting through the blood, the serum of which probably further enhances its effect. Any thoughtful student can do this and find why, for instance, the remedy would be less potent in effect upon the dense, firm, tubercular infiltration in the larynx, and most effective upon recent young tubercular tissue in the lung.

While the animal experiment and theoretical considerations in the light of the histological and pathological changes in the disease under consideration are necessary as a basis for all new therapeutical procedures, the clinical results, as we observe them in our patients, must still remain our chief guide for the estimation of the value of a remedy, whatever it may be. Having now a year of such clinical experience behind me, during which I have treated nearly a hundred patients with antipthisin, and having had as good opportunity as a special institution under most careful observation of the patients in the light of a considerable previous experience can afford, I can only say that my conviction as to its clinical value has steadily grown stronger, and that I have uniformly observed favorable changes in the tubercular processes, often to their entire disappearance, in the lungs of my patients, with return to normal conditions, where percussion and auscultation had given every evidence of a pathological state before its application.

I have further seen the rapid involution of the tubercle bacilli in the sputum, and their entire disappearance from it while the sputum was still purulent, in early stage cases; I have not observed their return in such sputum upon subsequent examinations when continued until no more expectoration was available. On the other hand, I have seen the persistence of consolidation, or only partial clearing up of the percussion note, or noted no apparent change at all, especially in old lesions and over cavities, and I have explained this by the fibroid changes which were evidently present. In cases with cavity the tubercle bacilli have been much more persistent, and degenerative forms did not appear as early in globular or cavernous sputum. It is similar with the fever, but most encouraging as to the specific effect of the remedy has been its success in acute cases, of which I have had four among my patients.

In one case acute and general dissemination had occurred from an older circumscribed focus, in the other three cases only diffused acute processes were present in both lungs, and all four had continuous temperatures between 102° and 105° F. All the patients dated the beginning of their illness from within two months, and severe anæmia, exhaustion, and rapid emaciation were well-marked symptoms. In every one of these cases the fever began to decline within the first two weeks; it soon became intermittent, and after a month or six weeks it was so far controlled that it rarely reached 100° F., while the local and general improvement of the patient was satisfactory in the highest degree. One patient is discharged apparently cured, the three others are still under treatment and are steadily improving.

In the early stages of the chronic form I have without exception seen the same favorable course. On the other hand, I found the temperature less influenced in cases which had suppurating cavities, or which presented evidence of cheesy pneumonic processes, with or without apparent softening and progressive destructive changes. The local and general improvement in such cases was, as a rule, less evident, although some portions of the consolidation present cleared up in almost every case treated. In quite a number of such advanced cases the improvement became more manifest as the treatment was continued and led to satisfactory restoration of the general health and apparent arrestment of the local disease justifying their discharge.

With this clinical evidence in my own cases, and with corroborating statements by all other practitioners who have used the remedy for a sufficient length of time, I believe that I can conscientiously recommend its trial to the profession, especially since I have seen not the slightest indication of any harmful incidental effect.

In conclusion, I would once more call attention to the necessary limitations of the remedy which suggest themselves from a full consideration of the pathology of tuberculosis, especially of the advanced stages, and which my experience has shown to exist. If we bear these in mind we shall not expect to accomplish the impossible nor shall we be likely to suffer disappointment.

MODERN TREATMENT OF LARYNGEAL AND PULMONARY TUBERCULOSIS.[1]

By J. W. GLEITSMANN, M.D.,

NEW YORK.

THE subject submitted to your consideration this evening is of such importance and magnitude that I felt some embarrassment as to how to present it to you without too great a tax on your time and patience. In order to keep the paper within the necessary limits it was found advisable to eliminate all details, and to merely touch upon the salient features of some points which otherwise would deserve a lengthy consideration. By the courtesy of our esteemed President, permission has been granted me to turn over the larger part of the pulmonary therapeutics to my friend, Dr. von Ruck, who, on account of his large experience, enjoys special facilities to do the subject justice.

Historical Sketch.—The treatment of laryngeal and pulmonary tuberculosis has undergone such a radical change in the last half of our century, that the advance science has made and the advantages patients have gained will be better appreciated if you will permit me to devote a few remarks to the development of our present therapeutics of the disease. As long as it was considered doubtful that consumption could be cured, palliative measures were *en vogue*; equable, warm climates were recommended, among which the Isle of Madeira enjoyed the special favor of our English confrères; the whole treatment was a more passive one, and consisted largely of guarding against injurious influences. About the beginning of the last half of the present century, publications of climatologists appeared in quick succession, stating the decrease of phthisis at high altitudes. Their statements were soon followed and confirmed by those of medical writers, who observed the beneficial effect of a prolonged sojourn in these regions. Among the former I will mention Fuchs,[2] Jourdanet,[3] Hirsch,[4] and Archibald Smith;[5] among the latter, Herman Weber,[6] Charles R. Drysdale,[7] Lombard,[8] and Biermann.[9] In 1854, Brehmer

founded his sanitarium for consumptives at Goerbersdorf, Silesia, and although starting from the wrong premise, that an abnormal smallness of the heart was the principal cause of consumption,[1] he obtained excellent results by his method of treatment. Of nine hundred and fifty-eight consumptives treated by him during the first fifteen years, twenty per cent. were permanently cured. His method was based on the principle of tonic and roborant treatment, and consisted of the freest possible use of pure mountain air, proper diet, methodic exercise, and hydro-therapeutics, with such constant supervision of the patient as is only possible in an institution. His success stimulated the foundation of other institutions on similar principles, to which I also committed myself (1874) and adhere to to the present day.[2, 3] About the effects of and the results obtained with tuberculin, tuberculocidin, etc., you will hear in a later part of the paper.

Progress in the treatment of laryngeal tuberculosis was much slower. The words of Tobold, 1866,[4] that "in the majority of cases the prognosis is very unfavorable," were repeated by Mackenzie, 1880,[5] who says: "The prognosis of laryngeal phthisis is always extremely unfavorable, and it is not certain that any cases ever recover."

The treatment was symptomatic and remained unsatisfactory, although some remedies recommended at this period are still in use at the present time, with varying success. A great advance was made when Krause announced his results obtained by applications of lactic acid.[6] The first series of observations from the lactic-acid treatment in this country was published by the author, in the New York MEDICAL RECORD, 1886.[7] Krause was followed by Heryng,[8] who introduced the surgical treatment as it is now practised.

Laryngeal Tuberculosis: Local Applications.—Although careful attention to the general condition of a patient suffering from laryngeal tuberculosis is indispensable, I shall not touch on this part of the treatment, but shall speak of the local treatment only. Disinfecting and anodyne sprays and insufflations are extensively used up to the present day. Intra-laryngeal injections of twenty per cent. menthol in an oily solution were first practised by Rosenberg,[9] and lately an addition of two per cent. of guaiacol to the menthol solution is well spoken of by English authors. In the opinion of the writer, the best results in laryngeal ulceration—aside from curettage—are obtained by the proper and judicious application of lactic acid. In making this statement we must not lose sight of the fact that in laryngeal tuberculosis we have to deal with a most intractable disease, and which until lately was generally regarded incurable. As isolated cases of a spontaneous cure are known to occur, and as relief can be afforded and even an apparent cure effected by different remedies, a long period of observation of the patient and an extended trial with the remedy mentioned is necessary in order to become convinced of its efficacy. Very appropriately the late Gottstein says in the last edition of his book on diseases of the larynx: "The physician who discards lactic acid after a few unsuccessful trials will not be able to form an unbiassed judgment; only one who uses the method systematically for a longer time will achieve better results with it than with any other method of treatment."

For the introduction of the acid, special instruments have been devised, but an ordinary good laryngeal cotton-carrier will answer the purpose. The acid must be rubbed into the ulcer with a moderate degree of force, and the strength of the solution employed should be gradually increased from twenty to seventy-five or eighty per cent., or even the full percentage. As a rule, an eschar is formed, which, when exfoliated, leaves a clean ulcer, showing a tendency to cicatrization. Contra-indications are a high degree of hectic, far-advanced destruction of lung tissue, or extensive ulcerations of the lower larynx and trachea.

The connecting link between local applications and surgical treatment are sub-mucous injections. As lactic acid is only efficacious in the treatment of ulcerations, and does not act on parts covered by intact mucous membrane, infiltrations must be treated in a different manner, and they can be reduced by sub-mucous injections. Quite recently, such injections with an oily solution of creosote, two drachms to the ounce, have been highly lauded by Dr. Chappell, and if further experiments confirm his results we shall have in creosote a fair rival of lactic acid for this purpose. There is a difference of opinion as to the length of time which should be allowed to intervene between each injection, as well as to the strength of the solution. In my cases I had the best results from injections of five to eight drops of a fifty per cent. solution of lactic acid, which were not repeated until the usually large eschar had sloughed away; this it generally does in from six to ten days. Although ingeniously constructed syringes for this purpose are in the market, an ordinary good syringe, with a properly curved laryngeal attachment and a good point, accomplishes everything that is desired. I have found injections most useful and beneficial in large, club-shaped thickenings of the arytenoids, giving rise to distressing dysphagia, and in such cases, I prefer them as a rule to either curettage or excision, as the latter are much more trying and painful to the usually weak and emaciated patients.

Surgical Treatment.—We now come to the surgical treatment, which is threefold, consisting of either incision, curettage, or excision. The idea of surgical treatment in laryngeal tuberculosis emanated from the reports of the good results obtained by surgeons in the treatment of tubercular affections in more accessible regions of the body. Incisions into the infiltrated parts, especially in the region of the epiglottis and the ary-epiglottic folds, were first practised by Moritz Schmitt,[1] who observed lessening of the infiltration and subsequent relief in a number of cases. Curettage and excision, by far more frequently employed, especially on the continent, were first practised by Heryng, who, in conjunction with Krause, worked indefatigably to improve this method. Curettage is indicated in ulcerations, while excision is better adapted for infiltrations. By the former the ulcerations are scraped until the diseased tissues are entirely removed, and then lactic acid or iodoform is applied. By excision the infiltrated parts are cut away until healthy tissue is reached.

The three sets of instruments I present to you for inspection plainly show the vast improvements that have recently been made in this direction. For operations in the sub-glottic space, Scheinmann's forceps is an excellent instrument. The contra-indications to surgical treatment, as enumerated by Heryng, are, advanced pulmonary disease, diffuse miliary tuberculosis of the larynx, severe stenosis of the larynx, when tracheotomy is indicated, and lastly irritable, distrustful patients, who lack the necessary fortitude and perseverance.

It would carry us too far to speak of the technique of operating, or to enter into the literature and controversies which this treatment has elicited among different writers. Sufficient to say that Heryng, who un-

doubtedly has the largest experience, has treated in this manner 268 cases from 1887 to 1894. Of this number, 20 patients were cured; in 8 of these the cure has lasted over four years; in 8 over two years, and in 4 over one year; altogether about 13.5 per cent.[1] Although the number of cures may appear to you extremely small, it must not be forgotten that by this treatment many distressing symptoms, *i.e.*, dysphagia, etc., can be alleviated and even permanently relieved, although the patient may die later on. Laryngeal tuberculosis is so fatal a disease that we can congratulate ourselves if we succeed in curing even a very small percentage of our cases. One of my patients shows the destructive lesions of the larynx and the pharynx as they appeared when the disease had reached its climax. He is now strong and well, seven years after the appearance of the disease. Even if I had never succeeded in relieving another patient, she would nevertheless prove a living example of the benefit to be derived from surgical treatment, without which she undoubtedly would have died years ago.

For the sake of completeness I shall mention electrolysis, tracheotomy, and extirpation of the larynx on account of tuberculosis, but time forbids me to enter into the merits and indications for these measures.

Pulmonary Tuberculosis; Climatic Treatment.—As we have at the present time no reliable means to cure tuberculosis by home treatment, patients who can afford it and in whom the disease is not too far advanced had better go to some climatic resort. When we consider the bewildering number of such places, with their diversity of climate, all laying claim to certain beneficial influences on patients, the question of where to send a patient in a given case is a very perplexing one. As the treatment of tuberculosis is now conducted more on stimulating than sedative principles, we naturally look for a climate with pure, bracing atmosphere, which we are more apt to find in mountainous regions than in the lowlands. There will always be a large class of patients who are better suited in warmer, southerly latitudes, patients who feel uncomfortable at the slightest change of temperature, or who are too weak to take even a moderate amount of exercise, and who require a warm atmosphere in order to be able to remain outdoors. The degree of elevation depends somewhat on the preference of the physician and the condition of the patient. Without going into details, we can say that patients with chronic infiltrations or stationary lesions will get along very well at higher elevations, while those with active processes, a weak heart, and a tendency to hemorrhages are better suited in lower regions. It would carry us too far to enumerate the different health-resorts, and I shall mention only a few types. We see good results from a sojourn in the high alpine regions in Switzerland, *i.e.*, Davos, St. Moritz, as well as in the lower resorts of middle Europe. In our country, Colorado, with an elevation of over five thousand feet, was primarily settled by miners and consumptives. On the other hand, the Adirondack Mountains in our State and the southern extremity of the Blue Ridge have earned a well-deserved reputation. The latter covers a vast area, and comprises the Cumberland plateau in Tennessee, the whole western North Carolina, and adjacent portions of Georgia and South Carolina.

In spite of all that has been said the selection of a proper place for the patient will always require great circumspection, good judgment, and a fair climatological knowledge on the part of the physician. Wherever we may send our patients, a prolonged stay—not a sojourn for one season only—will be necessary to relieve this treacherous disease.

I cannot close my remarks with a more fit sentence than to quote the words of the late Niemeyer, who said: "The chief desideratum is that patients, wherever they are, should live carefully and remain under the supervision of an intelligent, conscientious physician."

MYXŒDEMA TREATED WITH THYROID EXTRACT—REPORT AND PRESENTATION OF A CASE.[1]

By R. ABRAHAMS, M.D.,

NEW YORK,

DISTRICT PHYSICIAN TO MOUNT SINAI HOSPITAL; VISITING PHYSICIAN TO MOUNT SINAI HOSPITAL DISPENSARY.

MR. PRESIDENT AND GENTLEMEN: At the last meeting of the Alumni your esteemed president called upon me to report my case of myxœdema. As the call was unexpected, and as my knowledge of the case at that time was yet incomplete, the report was necessarily meagre and devoid of the proper interest. To-night, however, I am in a position not only to give you a full and detailed account of the case, but, fortunately, am able to show you the disease in its relapse.

In the way of an apology for reporting to you only one solitary case, I wish to remind you that myxœdema, as yet, is a rare disease. Up to date, as far as I could ascertain, about seventy cases were reported here and in England. I say "as yet," for I believe the disease is not destined to remain, numerically, a clinical curiosity. Its recognition does not require extraordinary diagnostic acumen. Its oddness makes it extremely impressive. Once seen it can never be forgotten, and never be mistaken. Even less than seeing, if only a full and correct description of myxœdema were read or listened to, the mental picture would be such as to make one identify it wherever he met it. And just as soon as the profession learns, through one medium or another, to recognize the peculiar malady, the literature and the reports of it will be manifoldly increased. I would not vouch that, notwithstanding the already acquired fame of myxœdema, some men to-day treat it for chronic Bright's disease, anæmia, melancholy, or obesity. My own observation of myxœdema led me to suspect two elderly women whom I recently saw waddling along on the East Side, who looked to all appearances myxœdematous. A friend, a physician, told me the other day that he diagnosticated a myxœdema riding in a horse-car.

A point which is not generally known about myxœdema is the plausible assumption that it is a new disease, that thirty years ago the disease was not only unknown, but that it did not exist at all.[2]

CASE.—Mrs. S——, aged twenty-nine, of small stature; a Jewess, and a native of Poland. Her family history presents nothing of special significance, except that her oldest child has hip disease. Her personal history is as follows: While a child, she went through all the diseases peculiar to childhood, leaving her health unimpaired. At fourteen menstruation appeared, which was always regular and painless. At seventeen she entered upon her nuptials. During the first three years of her marital life she suffered three miscarriages; in the fourth year, however, she was more fortunate—she carried to full term. This was followed by two more successful pregnancies, her health remaining good.

Two years ago she lived on the outskirts of a village near a forest. Having been often left alone in the house, exposed to the influence of dreary woods, her mind became full of apprehensions, dangers, and terrors, and her nervousness steadily augmented. The last straw that broke her down completely was a shock that she sustained at the unexpected sickness of her oldest boy. Almost immediately after, her face suddenly became swollen; the swelling was so enormous that the eyes and nose were unrecognizable. This condition, while lasting four weeks, caused no pain whatever. With the dis-

[1] Read before the Alumni Association of the Mount Sinai Hospital, November 27, 1894. Patient was also presented at a meeting of the New York County Medical Association, May, 1894.

[2] International Clinics, vol. ii., second series, page 8.

appearance of the swelling, the woman began to lose flesh and strength until she was reduced from corpulency to a mere skeleton. Five months later her face began to swell again, but this time the process was gradual. At the same time with the swelling she felt pricking sensations in her fingers and chilly sensations all over the body. Gradually she began to observe that her hands, legs, and body were assuming an unusual size, and that her memory was getting treacherous. These symptoms were slowly but steadily progressing until her husband and friends became alarmed, and finally sought medical advice. I saw her for the first time in April, and the clinical picture she then presented is as follows: Marked œdema of the forearms, hands, legs, and abdomen.

Fig. 1.—Before treatment.

The œdema of the face was not so pronounced. The œdema in the abdominal walls felt in some places as if it were sacculated, for I could lift up and compress it like a semi-solid tumor. In particular parts, as on the legs, the œdema pitted on pressure, but generally it did not. The swelling of the hands was so great that their closure was a mechanical impossibility. The fingers were characteristic, short, stubby, and spade-like. The nails were brittle and discolored. The œdema of the legs did not go beyond the ankles, but it reached an extreme which made it impossible for the poor victim to put stockings on, and when she did succeed in adjusting dilatable coverings, she was loath to remove them; and like the Jews in their forty years' wandering through the desert, the leggings grew with her legs. The toes were in no way affected. The skin was pale, dry, and where the œdema was greatest, it was covered with rough scales. Perspiration was totally absent in spite of hot weather, hot baths, or exhausting work. She was keenly susceptible, however, to cold, and she invariably felt better in the warm season. She had some of the facies of myxœdema, namely, arched brows, flattened nose, deep sunken, peculiarly glistening, eyes; thick lower lip, and though being anæmic, there was always a circumscribed flush on her cheeks. The total expression of her face was stupid and listless. The tongue was coated, flabby, and hypertrophied; it filled the whole mouth, made speech slow and dragging, and swallowing difficult. The gums were spongy and the teeth wide apart. Stomach and intestines presented signs of a mild dyspepsia. The disease, however, seemed to have chosen the intellect for its special target. There was a complete loss of memory, and as she was in business, engaged in buying, selling, and especially trusting, you can easily imagine her prosperity. Logical reasoning was out of the question, for before she arrived at the conclusion the premises were a thing long forgotten to her. When she did not work, she was sleeping, and when she did work, she was dozing. Constant drowsiness seems to be a special feature of myxœdema. She had no mental aberrations while awake, but at night her sleep was disturbed by nightmare. As she lived, moved, and had her being in a continuous dream, this, perhaps, more than her odd physiognomy, made her look stupid and indifferent. Her hair was dry and shaggy, but there was no falling out of it on the head, while there was a complete emigration in the axilla and pubis. Sight and hearing were somewhat impaired. Dr. Carl Koller, to whom I am indebted for examining the eyes, found nothing in them of especial character. The electrical test of the muscles, which was kindly made by Dr. Leo Steiglitz, was found to be normal, save in muscles which were covered by marked œdema, where the reaction was a little slower. Reflexes were normal. The heart was slow, but the apex-beat was proportionately strong. The lungs normal. The temperature ranged between 97° and 98° F. The blood indicated a condition of anæmia, and the urine, from time to time, contained a trace of albumin, a diminution of urea, and an absence of casts. Menstruation was regular but scanty; anaphrodisia, strange to say, was a symptom prominently mentioned by the patient herself. Her gait was of the waddling kind, and her movements lazy and laborious. While she complained of pricking sensations in the tips of her fingers, the skin overlying them was more or less anæsthetic. Areas of anæsthesia were found on the lumbar and cervical regions; there was also complete anæsthesia of conjunctiva and pharynx. In the place corresponding to the thyroid gland there was a deep depression, enough to hide my fist. Such was the condition of my patient when I first saw her in my office in the middle of April, 1894.

Fig. 2.—After treatment.

The photograph (Fig. 1) that is passed around was taken by Dr. George H. Fox, to whom I am exceedingly thankful. A better and more characteristic picture was taken of the more remarkable hands, but was, unfortunately, lost.

For certain reasons I toyed with the disease until May 23d. On that day the woman was put on thyroid extract (Parke, Davis & Co.). The initial dose was five grains in a capsule. And I may say here at once that I could not increase this daily dose by even one grain without producing distressing headaches and troublesome palpitation of the heart. Besides, there was no need nor justification to push the dose farther, as the five-grain dose was all-sufficient. The effect of the first capsule was so gratifying to her, that, like Oliver Twist, she cried for more. Within one week, that is, after taking thirty-five grains of the extract, she could move and bend her formerly unwieldy fingers; could pull off her stockings easily; memory improved; speech, sight, and hearing were very much better. The only undesirable occurrence during the first week's treatment was the development of acute pain in the knee-joints, and extremely tender, reddened areas over the tibiæ, resembling very

much erythema nodosum. All that, however, quickly yielded to phenacetin. At the end of the second week, that is after taking seventy grains of thyroid, the patient's skin was bathed in perspiration; the tongue moved as fast as in the good old days; her bodily movements, general appearance, and mental activity were so changed that for the first time she began to realize how clumsy and awkward she had been. The event of the second week was deepened anæmia and headaches, which were, however, more or less successfully combated by the albuminate of iron. The thyroid was continued for a month longer, the dose remaining the same. At the end of this time, the woman was perfectly well. And what a change! Without having seen her, you can hardly appreciate it. She had lost by actual weight thirty pounds during the six weeks; and the face, while not the dream of an artist, still was smooth and shapely; intellect clear; memory retentive; regions that were rendered barren once more resumed their hairy growth; and last, but not least, the woman that was for three years sterile now became pregnant. From that time on the treatment was irregular; the patient feeling well saw no need for taking medicines; yet I forced her to take ten grains a week to prevent a relapse.

On September 13th I treated her for abortion; and since then, up to the middle of this month, I did not see her, during which time she took no medicine, and therefore got a relapse.

To complete the clinical picture I should mention the fact that the temperature from the beginning of the treatment up to the last day was never higher than 99° F., while at times it was normal. The urine from the first day on was larger in quantity, higher in specific gravity, more acid in reaction, and rich in urea.

Now, gentlemen, as this was a typical myxœdema, and as its cure was so rapid and effective, I need hardly impress you with the value of that wonderful animal extract. And I may be permitted to say here that all talk to the contrary seems to indicate either a false diagnosis or a spurious drug. Personally, my confidence in the action of the thyroid extract is so great that if a supposed myxœdema did not improve on a reliable preparation of thyroid extract after one week's trial, I would unhesitatingly exclude the diagnosis of myxœdema.

The excellent result I had with thyroid extract seems to be different from that of a good many other observers, inasmuch as the improvement and cure of my case were uniformly good and rapid. My reason for it is that the patient's progress was not interrupted by any delaying complication, as the experience of others was in their cases. I did not discontinue the treatment for one day, as there was no contra-indication to such a procedure whatever. The reason for the absence of any complication seems to me to be that, since I was satisfied with the purity and reliableness of the extract, I did not push it to the point of intolerance as others did. I believe that a five-grain dose a day is sufficient and effective.

I think it is preferable to employ a powder to a tabloid, for the latter necessarily has a fixed dose—a feature highly objectionable, especially when you are anxious to make your daily dose larger. A point worthy of mentioning, and one worthy of adopting in the treatment of myxœdema, is to put the patient from the start on some form of iron in connection with the thyroid. This additional measure will, to a great extent, prevent or control the otherwise unavoidable anæmia that goes along with the disease and its treatment.

In the beginning of my paper I promised to show you the patient, but I ask you, please, not to expect to find a full-fledged myxœdema. You will find, however, a commencing relapse, with initial symptoms such as chilly sensations, loss of memory, difficult speech, and some œdema. A month longer, and I should expect you to see the disease pretty well developed.

Now with a specific for the disease at our disposal we may, for a moment, complacently look back and see how, but a short while ago, the disease was treated. "Hot bath every evening and twenty grains of bicarbonate of soda in water three times a day." Next came jaborandi, and while improvement in some cases did follow the long and faithful administration of this drug, yet the victims were never cured, nor ever markedly relieved. Nitroglycerine also entered the therapeutics of myxœdema. The theory upon which these two agents were employed was best explained by Dr. David M. Finley, of London.[1] He says: "Seeing that a diminished excretion of urea is one of the characteristic symptoms of the disease, we may take it that an increase is so far an indication of improvement, and it is interesting to compare the effect in this particular of the jaborandi and the nitro-glycerine respectively." The comparison shows a greater excretion of urea under jaborandi than under nitro-glycerine. This was then the very best treatment. The same writer concludes with the remark: "As to the prognosis, the tendency of the disease is toward a fatal result." What a change in the treatment, and what a difference in the prognosis! I think we can positively assert to-day that myxœdema can be cured, and that we can promise immunity from relapse, provided the patient puts herself to the inconvenience of taking five or ten grains of thyroid extract every week.

The discovery of the treatment exceeded in importance that of the disease. It opened a rich and vast field of possibilities. Who can tell but that in a short time most if not all of our therapeutics will be made up of animal extracts? If only every decade added a specific to our stock of remedies, such as we find in thyroid extract, the sarcastic but true remark of our departed colleague, Oliver Wendell Holmes, would have to be reversed, and say: "If all the medicines were thrown into the ocean it would be good for the fishes and bad for men."

156 Clinton Street.

SOME OBSERVATIONS CONCERNING A NEW TEST FOR THE DETECTION AND QUANTITATIVE ESTIMATION OF FREE HYDROCHLORIC ACID IN THE GASTRIC JUICE.

By JULIUS FRIEDENWALD, A.B., M.D.,

BALTIMORE, MD.,

CLINICAL PROFESSOR OF DISEASES OF THE STOMACH, COLLEGE OF PHYSICIANS AND SURGEONS; VISITING PHYSICIAN, BAY VIEW HOSPITAL.

The examination for free hydrochloric acid is of great importance in the diagnosis of diseases of the stomach; it is therefore necessary that the simplest as well as the most reliable methods for the estimation of this acid should be known. A new reagent has been recently described as reliable and simple. It is dimethylamidoazobenzol, and was first introduced into acidimetry by B. Fisher and G. Philipp;[2] it is highly recommended for the estimation of free hydrochloric acid in the gastric juice by G. Toepfer.[3] Toepfer uses the reagent as follows:

A 0.5 per cent. alcoholic solution is prepared. Three to four drops of this solution are added to the gastric filtrate. If a reddish color is produced free hydrochloric acid is present, if a yellowish discoloration, it is absent. For quantitative work, 5 to 10 c.c. of gastric filtrate are placed into a beaker. Three or four drops of the dimethylamidoazobenzol are added and the mixture is then titrated with a decinormal sodium-hydrate solution until the reddish color entirely disappears and the fluid becomes yellowish. The number of cubic centimetres of $\frac{1}{10}$ normal NaOH em-

ployed in this process for 100 c.c. of gastric filtrate multiplied by .00365 equals the percentage of free hydrochloric acid present.

Inasmuch as the phloroglucin-vanillin test of Günzburg[1] and the resorcin test of Boas,[2] are very accurate reagents for the detection of free hydrochloric acid, it is necessary that any new substances for the detection of this acid should at least be as accurate as the above-named. The following conditions must therefore be fulfilled :

1. The reagent must only react to free mineral (hydrochloric) acids, and to very small quantities of the same.

2. It must not react to organic acids or other substances likely to be present in the gastric contents.

Our first observations were made to determine the limits of accuracy of Toepfer's new reagent. Solutions containing known quantities of pure hydrochloric acid were prepared and tested in turn with phloroglucin-vanillin resorcin and dimethylamidoazobenzol. According to our earlier observation[3] 0.005 per cent. of hydrocloric acid can be detected in pure watery solution, when tested with resorcin, 0.004 per cent. with phloroglucin-vanillin ; we have determined that 0.004 per cent. of hydrochloric acid can be detected with dimethylamidoazobenzol. This reagent is thus as sensitive to hydrochloric acid as the others. Inasmuch as the presence of other compounds, such as peptones, prevents the detection of higher percentages of hydrochloric acid by the phloroglucin-vanillin and resorcin tests, it was necessary to determine whether the same is true respecting the new reagent. Certain substances, such as albuminous compounds, combine with a part of the hydrochloric acid and neutralize it ; in the examinations compiled in the following table we were therefore obliged to obtain the absolute quantity of free hydrochloric acid by a very accurate method, not relying on the quantity of hydrochloric acid added to the mixture. According to Kossler[4] the most accurate method is the calcium carbonate test of Leo, and this was employed for comparison.

Substances in combination with the watery solution of HCl.	Percentage of HCl at which a reaction may still be obtained.			
	Leo's $CaCO_3$ Test.	Resorcin.	Phloroglucin-vanillin.	Dimethylamidoazobenzol.
Water	0.002	0.005	0.004	0.004
Acid potassium phosphate, $\frac{1}{10}$ alkali	0.009	0.07	0.04	0.01
Albumin, 1 AL + 200 H_2O	0.003	0.08	0.06	0.01
Peptone, 2 per cent	0.003	0.17	0.17	0.009
Bread paste, 30 grammes to 200 c.c. H_2O	0.003	0.04	0.04	0.04
NaCl, 1 per cent	0.003	0.003	0.007	0.003
Grape sugar, 1 per cent	0.002	0.007	0.007	0.003
Starch paste, 2 per cent	0.003	0.01	0.01	0.009

These experiments show that the dimethylanidoazobenzol test is more sensitive than Günzburg's or Boas's, and that it may, therefore, be employed for the detection of small quantities of hydrocholoric acid in place of the former reagents. In point of fact, it is almost as sensitive as Leo's test.

In order to show that dimethylamidoazobenzol reacts to free hydrocholoric acid only and not to this acid in the combined state, and to make the conditions similar to those present in the stomach, the following experiments, as carried out by Toepfer,[5] were repeated : A 0.5 per cent. solution of egg albumen was prepared and 5 c.c. were placed in ten beakers (1 to 10) ; then 1 drop of $\frac{1}{10}$ normal HCl was placed in the first beaker, two drops in the second, and so on, ten in the tenth beaker. Into each beaker a fourth of a gramme of pepsin was added and then a lamella of blood albumin. The beakers were then placed in the thermostat at 40° C., and allowed to remain there for six hours. In beakers 1 to 5 the fibrin lamellæ, though swollen, were not digested ; the sixth showed slight traces of digestion, while in the remaining beakers the digestion was more marked, in the tenth the fibrin lamella being entirely dissolved. From each of the beakers portions were removed and tested for free hydrochloric acid with phloroglucin-vanillin, resorcin, and dimethylamidoazobenzol. The portions removed from the first six beakers showed no signs of free hydrochloric acid with any of the reagents, the portions from beaker 7 showed a slight reaction, while those from 8, 9, 10 showed marked reactions with all the reagents. It is therefore evident that dimethylamidoazobenzol reacts to hydrochloric acid when in the free state only ; inasmuch as hydrochloric acid was present in the first six beakers, it must have been in combination with other substances.

To determine whether dimethylamidoazobenzol gives a reaction to organic acids, solutions of various strengths of lactic and acetic acids were prepared from 0.05 to 1 per cent. and tested with the reagents. A reaction could only be noted when these acids reached a concentration of 0.5 per cent. when the yellow color changed to red ; this was the more marked the nearer the solution reached 1 per cent. It was found, however, as Toepfer has already pointed out, that when albumin or peptone were present in the mixture, even in small quantities, even greater concentrations could not be detected with this indicator. Thus only a 0.7 per cent. solution of these acids when added to an egg albumen mixture (albumen, 1 gramme ; water, 200 c.c.) gave a reaction with dimethylamidoazobenzol, and only an 0.8 per cent. when added to a 5 per cent. solution of peptone. It is therefore evident that while dimethylamidoazobenzol gives a reaction with organic acids, it does so when in such concentrations as are never present in the gastric contents. This fact does not therefore interfere with the accuracy of this test for the gastric juice.

In order to practically test the accuracy of this reagent for quantitative work we have made a number of quantitative estimations of the free hydrochloric acid in a number of specimens of gastric juice, comparing the results obtained by dimethylamidoazobenzol with those gotten by phloroglucin-vanillin[1] and Leo's method.

Number.	Acidity determined by phenolphthaline.	Percentage free HCl according to Leo.	Percentage free HCl according to Mintz.	Percentage free HCl by means of Toepfer's reagent.

20	87	0.30549	0.30082	0.30218

The last table shows that very accurate results are obtained by the use of dimethylamidoazobenzol. The examination is made as follows :

To 10 c.c. of gastric filtrate three to four drops of a

[1] Günzburg's reagent consists of phloroglucin, 2 ; vanillin, 1 ; alcohol absol., 30.

[2] Boas's reagent consists of resorcin resub., 5 ; sacchar. alb., 3 ; alcohol dilut., 100.

[3] The Use of the Resorcin Test for the Detection and Quantitative Estimation of the Free Hydrochloric Acid of the Gastric Juice. MEDICAL RECORD, October 6, 1894.

[4] Kossler : Zeitschrift für Physiologische Chemie, Bd. XVII., S. 107.

[5] Toepfer : Zeitschrift für Physiologische Chemie, Bd. XIX., Heft 1, 1894, p. 114.

[1] The method employed in using the phloroglucin-vanillin was that recommended by Mintz, Wiener klin. Wochenschrift, 1889, No. 20, and 1891, No. 9.

0.5 per cent. alcoholic solution of dimethylamidoazobenzol are added; if free hydrochloric acid is present, the mixture becomes red. It is then titrated with a decinormal sodium-hydrate solution until it turns distinctly yellow. The number of cubic centimetres of $\frac{1}{10}$ decinormal NaOH employed for 100 c.c. of gastric filtrate multiplied by 0.00365 gives the percentage of free hydrochloric acid present.

If, for example, 7 c.c of $\frac{1}{10}$ normal NaOH had been used, then the amount of free hydrochloric acid is equal to seventy (for 100 c.c. gastric juice) multiplied by .00365, which equals 0.2055 per cent.

The total acidity of the mixture may now be determined by adding a few drops of phenolphthaline to the same mixture and titrating further with the $\frac{1}{10}$ normal NaOH solution until a red color is produced.

Inasmuch, therefore, as dimethylamidoazobenzol is a very accurate reagent for the determination of free hydrochloric acid, and as by its use the method of making quantitative examinations is greatly simplified, we highly recommend it for this purpose.

In conclusion, it is of importance to state that we have used filter-paper dipped into the solution of dimethylamidoazobenzol and allowed to dry, with great advantage, as a test-paper for the detection of free hydrochloric acid.

Progress of Medical Science.

The Treatment of Injuries of the Lower End of the Humerus.—Dr. Hutchinson (*British Medical Journal*) treats of the common fractures about the elbow-joint. The most frequent one is a more or less transverse fracture at or about the olecranon and coronoid fossæ. In subjects under ten years this will be a detachment of the lower epiphysis. Sometimes the chief feature of a fracture into the elbow-joint is the complete detachment of the articular surface of the radius, the special risk of which is the failure to secure bony union. Looking at the rapid supervention of swelling about the elbow that follows these injuries, it will probably be agreed that for the surgeon to effect a proper diagnosis and reduction he must administer an anæsthetic as soon as possible after the accident. In the treatment of these fractures the author advises against the use of all complicated splints and dressings, and favors a movable felt or tin splint. As to the position of the forearm, the author recommends moderate pronation, so that the thumb is up. Experiments show that either extreme pronation or supination tends to laterally displace the lower fragment of the humerus. The very commonly used internal rectangular splint provides for this position, but it is not an ideal one, as there is certainly a tendency with its use to have more or less lateral displacement of the lower fragment (especially inward). The author favors the position of flexion rather than extreme extension, because it is much easier to carry out, more comfortable for the patient, and has so far given the best results.

After certain fractures at the lower end of the humerus it may be laid down as a rule that bony union is not to be expected. These are mainly: 1. Fracture or separation of the epiphysis of the internal epicondyle. 2. Intra-articular fractures of the capitellum. The first is by far the most frequent, and, in the author's experience, the little fragment is almost invariably drawn down toward the ulna, and unites by fibrous tissue. Usually this displacement gives rise to but little trouble. Several cases have been reported where the displaced fragment pressed upon the ulnar nerve, causing ulnar paralysis. When the fragment is removed, recovery is usually complete. The capitellum when broken usually remains as a loose body in the joint, producing sometimes much trouble in movement. In neither of these fractures is any splint certain to be effectual. The only plan which promises bony union in good position is to fix the detached fragment with a needle or peg to the surface of the humerus from which it has been broken off. In the majority of cases passive motion should not be begun until about the end of the third week. As regards compound fracture, the old rule of primary excision is not to be accepted. The removal of all loose fragments and good drainage will give much better results.

In old cases of fracture about the elbow, where persistent limitation of movement remains, the cause is probably to be sought in one of the following conditions: 1. Pressure upon the ulnar nerve by projecting bone or callus. Time and massage usually overcome this difficulty. 2. Thickening of the capsule in front and behind, with abnormal adhesion of muscles surrounding the joint. To be relieved by massage and passive motion. 3. Intra-articular fibrous adhesions or alterations in the cartilaginous surface of the trochlea. 4. Actual bony impediment to flexion.

The Celestial Method of Detecting Opium.—In the forty-second issue of the "Chinese Imperial Maritime Customs Medical Reports," published at Shanghai, Dr. George R. Underwood gives an interesting account of the medico-legal method employed by the Chinese mandarin for the detection of opium in the corpse of a person alleged to have died of the poison. We commend it to our chemists for its novelty and the ease of its carrying out; leaving its accuracy to the test of time, experience, and medico-legal wisdom.

There had been sorrow and confusion in the family of Huang-Hu. The mother, a woman (for even in China the mothers are women), was dead. The questions were, why did she die? how did she die? and, perchance, by whom did she die? So the court of the mandarins was assembled. Under the stern direction of the mandarin judge, the mouth, nostrils, vagina, and rectum of the unprotesting corpse were tightly plugged with wet paper, and two probes of untarnished silver, about twelve inches long, were passed for nearly their full length—one into the rectum, the other into the mouth. Next, the head and trunk were wrapped in sheets of wet paper, the whole body enveloped in quilts, and boiling water, kettleful after kettleful, was poured as quickly as could be procured over the corpse. The temperature was 95° F. in the shade; the afternoon sun was broiling hot; dinner had been postponed; no wonder the temper of the Chinese mandarin was only prevented from boiling over by a series of acrid remarks to the corpse, the attendants, and the world in general. The pouring and the objurgations went on *pari passu* for an hour and a half, when the face was uncovered, and the probe passed in through the mouth found to be untarnished. After sundry head-shakings and expostulations, the probe was replaced; again the stream of heated water and heated words splashed on the bystanders until another fifteen or twenty minutes had passed, when the mouth probe was again brought to light; and in its blackened surface celestial wisdom read the story of opium poisoning; a story which received further confirmation when from the uncovered swollen body the rectal probe was taken out and found badly stained.

After it was shown that the woman truly was dead of opium, the hunt grew hot for the author and source of the poisoning. The sleuth-hounds of the Law Department of the University may well be interested in the unwindings and outgoings of the court hereafter; but for the medical man the interest of the case ceases with the determination of the death; and so, as with the Lady and the Tiger, we leave unsolved the why, the wherefore, and by whom the death came.—*University Medical Magazine.*

THE INFECTIOUSNESS OF MILK.

EIGHT years ago the Massachusetts Society for Promoting Agriculture established an experiment station at Forest Hills, and undertook an investigation of the subject of the infectiousness of milk. The work was done under the direction of Dr. Harold C. Ernst, with Dr. Austin Peters, veterinarian, as first assistant. Much help was given also by Dr. Henry Jackson and Langdon Frothinghain, D.V.M.

The results were in the main reached in 1891, but the report was not written until November, 1894, and has just appeared from the press in a handsomely printed volume of one hundred and forty-one pages, with numerous illustrations. Though the title of the report is "The Infectiousness of Milk," we find that the investigations were confined to the question of tuberculosis.

The subject was studied along two lines: 1, As to whether cows with tuberculous udders could infect with their milk; and 2, whether cows with apparently or really healthy udders, but having tuberculosis elsewhere, could communicate their disease. As to the first question, there existed already sufficient facts to prove that the milk from a tuberculous udder was infectious. Most of the work was directed, therefore, to solving the second problem. In order to determine whether the infectious element of tuberculosis ever existed in milk from tuberculous cows whose udders were apparently healthy, inquiries were prosecuted under the following headings: 1. A careful and persistent microscopic examination of the milk from such cattle. 2. Inoculation experiments with such milk. 3. Feeding experiments with the same milk. In addition to these three main lines of investigation, there was also undertaken: 4. Similar investigations of the milk-supply of Boston; and 5. The gathering of as much evidence as possible from medical men and veterinarians as to cases of probable infection through tuberculous milk that had come under their observation.

There were one hundred and twenty-one microscopical examinations of milk and cream made, the specimens coming from thirty-six different animals. Bacilli were found in the milk from twelve animals, *i.e.*, one-third of the total. These animals were all infected with tuberculosis, but their udders were free from disease.

In addition to this, eighty-eight guinea-pigs were inoculated with the milk from fifteen cows, and tuberculosis developed in twelve guinea-pigs. Six out of the fifteen cows communicated the disease. Milk-feeding experiments were made upon rabbits, pigs, and calves. About four per cent. of the rabbits, fifty per cent. of the pigs, and thirty-three per cent. of the calves became infected.

An interesting investigation was made also of the general milk-supply of Boston. Among thirty-three samples from various sources, tubercle bacilli were found once; and among twenty-five rabbits inoculated with milk from mixed sources, three became infected.

One may infer from this that of the general milk-supply of a large city three per cent. or upward of the samples will contain bacilli and prove infectious.

The last branch of the inquiry was clinical in character. Circulars were sent to eighteen hundred medical men and veterinarians, asking if they knew of any cases in which human beings had been infected with tuberculosis through the milk of cows.

Among one thousand and thirteen replies from physicians, eight hundred and ninety-three were negative, eleven reported cases of infection by cow's milk, and eight reported cases of infection of a child by the mother.

The veterinarians gave much more striking evidence. Among fifty-four replies, fourteen reported positive, and nine suspicious cases.

The medical profession is quite ready to accept evidence of the dangers of milk from tuberculous cows; but the very thorough investigation made under the auspices of the Massachusetts Society places the matter on a positive basis, and furnishes ample ground for the most scrutinizing attention by boards of health to the subject of the milk-supply of the community.

THE URIC-ACID DIATHESIS.

THE morbid changes in metabolism known in a general way as the uric-acid diathesis have of late been the subject of valuable and important research. These investigations, and a plan of treatment based upon the newer view, are set forth by F. Levison, Kreisarzt in Copenhagen, in a work just issued,[1] entitled "The Uric-acid Diathesis." It is ably translated into English by Lindley Scott, and presents a logical summary of the latest information upon the pathology of uric acid and upon the action of drugs recommended in treatment.

Uric acid is one of the normal constituents of the urine, and nothing justifies the supposition that it is formed only in the kidneys. The reason why it is not found in the blood of healthy subjects is that present methods of analysis are not sufficiently accurate to detect it in the minute quantity of blood allowed to the analytical chemist by an apprehensive and blood-sparing public. What is the genesis and physiological signification of uric acid? How and where is it formed? The most complete and important researches into this question have been made by Horbaczewski and his pupils. Uric acid, as well as xanthin and hypoxanthin, can be prepared from spleen pulp. What constituents of the spleen can become decomposed into xanthin bases or uric acid? The nuclein of its lymphatics.

[1] Cassell & Co.

Outside the body, uric acid can be prepared from nuclein taken from any and every tissue. Does a similar decomposition take place in human beings? Investigations show that uric acid is increased when nuclein is taken as food or injected subcutaneously. It is probable, from Horbaczewski's experiments, that uric acid is formed in health by the disintegration of the nuclein which exists in different quantities in all the tissues. The amount bears a close relation to the number of white blood-corpuscles; for many observers have already demonstrated the fact that a temporary or permanent leucocytosis is always accompanied by a corresponding increase in uric acid or xanthin bases. Other new experiments show that the daily excretion of uric acid is comparatively independent of food. On the contrary, urea is proved to be entirely dependent upon the albumin consumed, rising and falling in proportion to the quantity of the nitrogeneous food digested. These investigations strongly indicate that uric acid is formed by the destruction and disintegration of all the constituents of the body. These processes are decidedly influenced by food; but not in proportion to the amount of albumin taken in. It is the urea excreted that can be doubled, or increased even in higher degree, through the agency of a large quantity of easily digestible albuminous material.

Do the urea and the uric acid excreted in urine stand in constant proportion? Haig has arrived at such an estimate, placing the normal ratio as 1 of uric acid to 33 of urea. This theory is completely overthrown by the experiments of Horbaczewski, Bleitren, Schultze, Hirschfeld, and Busquet. The excretion of uric acid in each individual is a fairly constant quantity, while that of urea has a wide range of variation. There exists, however, a constant proportion between the number of white blood-corpuscles and the amount of uric acid. The production of uric acid is increased in a whole series of abnormal conditions characterized by the formation and destruction of large numbers of leucocytes, as leucocythæmia, anæmia, pneumonia, carcinoma, and extensive burns. Certain poisons increase it: Carbon monoxide, pilocarpine, alcohol. Exercise also adds to its production.

Chemically and physiologically, it is usual to describe uric acid as a dibasic salt which can form neutral and acid salts with the alkalies. The researches of Roberts establish that normally uric acid exists in the blood as a quadriurate, and as such is excreted in the urine. Under special conditions the quadriurate is split up within the body into biurate and uric acid, and the latter is then eliminated by the kidneys; or the quadriurate may be transformed in the blood into biurate, which gives rise to the deposition of this difficultly soluble compound in different parts of the body.

The excretion of uric-acid is influenced by age, diet, physiological states, by medicines, poisons, and various diseases. The constitution of blood and urine may be so altered that uric-acid salts may be readily decomposed or deposited. All physiologists are agreed that an abnormal quantity of uric acid is found in the blood in gout; and all observations indicate that the gouty symptoms can arise only from this chemical constitution of the blood. Roberts's experiments show that an excess of uric acid in serum cannot remain long in solution. If the uric acid is not eliminated by the kidney, the increased quantity tends to its deposition in the body as a biurate. There are only two ways in which this overcharging of the blood by uric acid appears possible. It must either be formed so abundantly that some is stored up in the blood, although the normal quantity is still excreted, or, the production being normal or even diminished, an abnormal quantity is retained in the blood, owing to functional irregularities of the kidneys. Increased production of uric acid alone never leads to gout. Changes in the kidneys are more likely to be its cause. Recent observations show that the excretion of uric acid is likely to be less in daily amount in gout than in health. The kidney disorder need give rise, at its commencement, to very few anatomical changes, as the primary cause is a decrease in the secretory power of the kidney, whereby certain constituents of urine are less easily eliminated. Against this supposition that retention of uric acid is the origin of gout, the reply has been made that the disease would progress quickly and uniformly if this were the case. Why, when its production is so markedly influenced by various conditions and diseased processes, and when it may frequently return to the normal? The entire extent of the kidney is not simultaneously attacked. One kidney alone can take up the function of the other for a time. Though this pathogenesis of gout requires further proof, it has the advantage over other theories that it brings into one category all the etiological and pathogenetic factors with which we are acquainted, and gives a plausible explanation of the gout of wealth, the gout of poverty, and the gout of lead-poisoning. It also makes possible a rational form of treatment.

If the possibility of a retention of uric acid is once admitted, then every circumstance which causes a temporary increased formation of uric acid will naturally take effect, so that the blood can no longer hold in solution the quantity with which it is charged. The uric acid is then deposited as biurate, and the blood by this means rendered pure for some time. This is the explanation of feeling better after an attack of gout. If the deposition of biurate goes on slowly without hindering the circulation in the small lymph channels, the patient experiences but little discomfort during the formation of new tophi or the increase in size of old ones. When the deposition suddenly obstructs the lymph channels, pain and inflammatory symptoms set in, and a typical attack is established. In this manner the extensive use of alcohol or excessive bodily or mental work may precipitate an attack.

The biurate crystals become deposited chiefly in different kinds of cartilage, ligaments, tendons, skin, and subcutaneous tissues. The tissues bathed in synovia are especially liable to infiltration. The explanation of this, according to Roberts, is to be found in their chemical composition. The tissues rich in soda are earlier attacked than those which contain a smaller quantity of the salts of soda. Roberts gives the proportion of sodium salts in different tissues as follows:

Serum	contains	0.70	per cent.	sodium	salts.
Lymph	"	0.70	"	"	"
Synovia	"	0.80	"	"	"
Cartilage	"	0.90	"	"	"

Fibrous tissues	contain	0.70	per cent.	sodium	salts.
Blood-corpuscles	"	0.20	"	"	"
Muscles	"	0.08	"	"	"
Brain	contains	0.20	"	"	"
Spleen	"	0.04	"	"	"
Liver	"	0.02	"	"	"

Synovia, containing more sodium salts than serum or lymph, is also enclosed in a cavity with but little opportunity for movement or renovation. When saturated with uric acid, it can rid itself of the excess by depositing biurate crystals in the joint cavity. The knee and the metatarso-phalangeal joint of the large toe are chiefly affected in gout. These joints are particularly subject to strain; especially that of the great toe, which is more liable to injury than any other. Wounds, blows, and continuous pressure appear to predispose to gouty affections; and so also does a sedentary life without sufficient exercise. In other cases any hindrance to the circulation will favor the onset of gouty disturbance. Charcot reports gout in a hemiplegic in whom the joints on the paralyzed side only were attacked. At autopsies, sometimes no pathological changes are found in the joints, cartilages, fibrous tissues, etc., of persons who suffered severely from gout during life. Either the biurate has become again dissolved, or it has been deposited in tissues not examined at the autopsy, or in regions remote from joints. About the articulations autopsies may reveal biurate deposits that caused no pain whatever during life. Inflammatory phenomena and pain are brought about quite mechanically (Roberts), the biurate crystals acting as a foreign body, obstructing the lymph canaliculi, and giving rise to thrombosis.

Against the hereditary predisposition existing in many cases of gout, practically nothing can be done. Alcohol is fraught with peculiar dangers to those who have gout or a predisposition to it. Alcohol increases the production of uric acid, and by its continued use also diminishes the excretory power of the kidneys. Every form of prophylactic treatment which lessens the risk of kidney disease is indicated, as stimulation of the skin by baths and dry friction, woollen underwear, open-air exercise, gymnastics, and as far as possible an open-air life. Every over-exertion must be avoided. Excess in exercise is dangerous, because it can suddenly increase the production of uric acid to such an extent that the kidneys cannot excrete the amount produced, and thus acute attacks of gout may immediately follow.

Concerning diet there can be no fixed rules, except that of eliminating alcohol. A rational mixed diet, in which the usual nutritive elements are uniformly distributed, is the best. Sufficient and varied food is especially necessary after repeated acute attacks, or when the disease has become chronic. As the salts of lime and magnesia do not hasten the precipitation of biurate crystals in the blood, patients can be sent without hesitation to Nenndorf and Contrexeville. Sulphur springs can also be recommended. The best are those which contain a limited proportion of soda salts, as Gurnigelbad in Switzerland, Aix-les-Bains, and St. Sauveur. A mineral spring can be serviceable to the uric-acid diathesis in three ways: (1) by adding to the blood those substances which can keep the quadriurate in solution and unchanged; (2) by increasing the secretion of urine and the amount of uric acid eliminated by the kidneys; or (3) by strengthening the patient.

During the acute attack, interfere as little as possible. Warmth, rest, elevation of the part are classic measures. Lithia, piperazin, soda salts are perfectly useless; the latter are distinctly harmful. Trousseau notes that the bicarbonate of soda merely changes the typical attack into chronic malaise; and this opinion is shared by Golding-Bird and Owen Rees. Reference has already been made to Roberts's experiments, showing that soda salts always hasten the precipitation of biurate in serum. Colchicum shortens an attack, given when the pain begins to subside. It is said to invite a fresh seizure a little later; but this is often preferable to the half-chronic condition.

Ichthyol ointment sometimes relieves the pain. Opium preparations are always to be dreaded. Massage will hasten convalescence when only stiffness and pain are left. As soon as the patient can get up, judicious walking about and change of position will cause redness and aching sensations to disappear more rapidly than remaining in bed until all inflammatory symptoms are gone. A remedy that seems rational is potassium, either iodide, bromide, acetate, or carbonate. Roberts, in his experiments, found that all the salts of potash, irrespective of the acid with which they are combined, delay the deposition of the biurate outside the body. Abundant clinical evidence proves that this is also true within the human organism. Potassium salts are and must ever remain of peculiar value in the uric-acid diathesis.

What, then, in brief, is rational treatment based upon the newer view? Extreme care of the kidney; avoidance of sudden and excessive mental or physical effort; minute attention to the hygienic care of the skin; change of air and change of scene at stated intervals; an out-door life whenever possible; abundance of varied well-cooked food; plenty of pure water, but no alcohol; and the practical discarding of all drugs except potassium. In connection with diet, it is well to remember that sodium chloride is one of the substances which hold the biurate in solution. Several small meals, four or five a day, are better than a few hearty ones.

Urine is more acid after fasting; and the degree of acidity plays an important part in the pathogenesis of uric-acid precipitation. Hence the inadvisability of allowing twelve hours or more to elapse, from dinner to breakfast, without taking food. Dress is also important. It should be light, warm, perfectly fitting, and without constrictions about the joints.

The Ohio State Medical Society will hold its semi-centennial meeting in Columbus, on May 15, 16, and 17, 1895. It is proposed to celebrate the society's completion of fifty years of existence in a worthy manner. Members of the profession from other States are cordially invited to be present and assist in the exercises. The programme promises to be an interesting one. The president of the society is Dr. D. N. Kinsman, of Columbus, and the secretary, Dr. Thomas Hubbard, of Toledo.

SPRING SONGS.

The signs of spring appear. The colleges begin to "commence," and the medical societies are arranging for their annual meetings. Before the summer is over one hundred and forty medical colleges or thereabouts will have graduated classes, and forty-three State and Territorial Societies will have held their meetings.

These prospective occasions, though jocund and joyous to the individuals to be involved, have rather a dampening effect upon the vernal enthusiasm of the reflective. Each Commencement will be attended with music and oratory, flowers, fair women, and hopeful young men. We read each year of the glories of our calling, the industry and promise of our medical students, the disinterested and successful labors of the Alma Maters. But we think of the one hundred and forty individual Alma Maters, one hundred being superfluous and only fourteen being nutrient mothers for four years. The gestation, it seems to us, is too short and the lactation too tenuous to induce one to be jubilant about the offspring. The genius of the American medical Commencement is a woman, young, but emaciated by a rash polyparousness, haggard and wan over the multiple strain of inadequate lactations; insufficient for what she has, yet consumed with a desire for more. The old lady who lived in a shoe was a model of peace, plenty, and resourcefulness in comparison.

Our medical meetings give less concern, for at these the doctors often find how little the Alma Mater did for them. They meet and criticise and join in social reunions which brighten and broaden their lives. The readers of papers are doing themselves a good turn, the listeners expiate their sins, the medical journals publish, and many still retain their circulation. The medical societies this year, we notice, have all a promise of unusually interesting meetings, of valuable papers, and large attendance. We recollect reading these same words a year and also two years ago. It is the swan song of the secretary before his term expires and the doctor from another county is elected in his place. Every year it rings musically in the ear, and this spring, we notice, with a verity and forcefulness quite beyond precedent. We trust our medical societies will all have good and fruitful conferences during the coming season.

DISEASE AND FICTION.

The disciples of modern realism have searched heaven and earth, the sea and all that in them is, to say nothing of the waters under the earth, for striking subjects and harrowing details. More than this, and worse, they have invaded the realm of morbid conditions of mind and body, and have delineated the unlovely with an amount of patience and skill well worthy of a better and more æsthetic cause. A close acquaintance with human nature has always been considered necessary for the successful novelist. Nowadays it would seem that an accurate knowledge of pathology must be added to this equipment, and that in order to soar it is first necessary to sink. Our esteemed contemporary, the *American Medico-Surgical Journal*, says sarcastic and telling things in a recent issue concerning this unfortunate, though probably evanescent tendency, that has made of three fairly well-known books a presentation of symptoms rather than an artistic venture. The pulmonary record had another name, it is true; so also did the syphilitic novel and the morbid portrayal of defrauded instincts. There is danger in this medical movement. Young writers may attempt to cover too wide a field and forget the inexorable law of specialism. "To introduce a paretic or ataxic patient into a dermatological novel would not only destroy the unity of the story, but justly expose the author to a want of thoroughness. If the writer has determined upon appendicitis as his plot, he should not waste his energies upon irrelevant diseases in his minor characters. He could gain variety by introducing other forms of enteric disorders, but he should never exceed the limits of the abdominal region." And a sarcastic lament is made that, as yet, there exists no novel of the ear, no drama of the digestive organs, no romance of the kidneys, no pastels of the intestines. Blindness, idiocy, simple mania with delusions, visions and bright lights of hysteria and epilepsy, have each in turn served the modern writer of fiction. Later, it is not unreasonable to expect that several ailments in one book may further the general interest of the twentieth-century romance, when each department of pathology shall have its own special novel.

THE INTERNATIONAL LANGUAGE.

We have watched with interest the discussion that has been and is still going on in the pages of many of our contemporaries on both sides of the water relative to the vexed question of an international language. We have weighed carefully the arguments of our French brethren in favor of the adoption of their own exquisite tongue; we have read with the satisfaction of a duty done the letters upon this subject, many of them pointless and inconsequential, that have appeared in the *British Medical Journal*; we have pursued with a mournful interest a letter written by Billroth, almost on his death-bed, expressing a preference for Spanish next after English; we have listened with respectful attention to the editorial preferences of many of our esteemed contemporaries in this country, and we have not yet encountered any valid objection to modern Greek.

To judge from the tone of many of the criticisms one would suppose that this is a new idea, but such is by no means the case. Thirty years or more ago M. Gustave d'Eichthal, a learned Hellenist of Paris, argued at great length and most cogently in support of the proposition to adopt modern Greek as the common tongue of learned men throughout the world. One of his arguments was that an international language must be one that does not offend national prejudices, therefore neither of the three leading languages can be adopted, since whichever might be selected the patriotic pride of the other two nations would be wounded. In the case of modern Greek, however, this difficulty would not exist, since no nation could be jealous of another so insignificant territorially as Greece. But even d'Eichthal was not the first to make such a proposal, for Voltaire suggested the idea several times in his letters to the Empress Catharine of Russia at the

time when it seemed probable that she would take Constantinople and with it all the Turkish possessions in Europe. Those timid souls, therefore, who fear a new idea, whatever its merits, need not run from this one, since it is more than a century old, not to mention the many partisans of Greek who preceded Voltaire.

News of the Week.

Obituary Notes.—Dr. Josiah H. Gautier died, on April 1st, at his home in this city, after a long illness. He was in his seventy-seventh year.—Dr. John Adams Ryder, Professor of Embryology at the University of Pennsylvania, died, March 26th, of dyspepsia, in Philadelphia, after an illness of ten days. Professor Ryder was known as one of the foremost embryologists in the scientific world.—Dr. William S. W. Ruschenberger, a retired naval surgeon and scientist, died recently at his home in Philadelphia, aged eighty-seven. He was retired in 1871. He was an active worker in the Academy of Natural Sciences of Philadelphia, of which he was president for a number of years.

The Late Dr. Bernard E. Vaughan.—At a stated meeting of the Society of the Alumni of St. Luke's Hospital, held March 12, 1895, the undersigned committee was appointed to formulate and publish appropriate expressions of sorrow in reference to the death of Dr. Bernard E. Vaughan. In accordance with this authorization the committee have adopted the following preamble and resolution :

Whereas, In the wisdom of Almighty God it has been decreed to remove from among us our esteemed associate, Dr. Bernard E. Vaughan, who has been so thoroughly identified with the interests of the Society and with the work and advancement of the profession to which we belong,

Be it therefore resolved, That in the death of Dr. Vaughan we have met with a great loss, in one whom we valued as a friend and respected for his earnest and untiring work.

Resolved, That the Society extend to his bereaved family its sincere sympathy and condolence.

Resolved, That this preamble and resolution be entered upon the minutes of the Society, and be published in the New York MEDICAL RECORD and the New York *Medical Journal*.

WILLIAM H. CASWELL, M.D.,
THOMAS S. SOUTHWORTH, M.D.,
J. VAN DOREN YOUNG, M.D.,
Committee.

New Medical Law in Montana.—The Legislature of Montana recently passed a new medical practice act, in which many of the defects of the old law, which rendered the prosecution of offenders almost impossible, are remedied. Applicants who shall have been graduated after July 1, 1898, will be obliged to show proof of having attended four courses of lectures, of six months each. The board of examiners will meet in Helena on the first Tuesday of April and October of each year, and at such other times and places as the board itself may determine.

The Archives of Pediatrics.—With the May issue of this journal, it passes under the editorial charge of Dr. Floyd M. Crandall, recently managing editor of *Gaillard's Medical Journal*.

State Medical Societies.—The following State societies hold their annual meetings in April : Medical Association of Montana, April, 1895, Anaconda, Mont.; Medical Association, District of Columbia, April 2, 1895, Washington, D. C. ; Tri State Medical Society, April 2–4, 1895, St. Louis, Mo.; Tennessee State Medical Society, April 9, 1895, Nashville, Tenn.; Mississippi State Medical Society, April 10, 1895, Jackson, Miss. ; Florida State Medical Society, April 16, 1895, Gainesville, Fla.; Medical Society of the State of California, April 16, 1895, San Francisco, Cal.; Medical Association of the State of Alabama, April 16–19, 1895, Mobile, Ala.; Iowa State Medical Society, April 17, 1895, Creston, Ia. ; Medical Association of Georgia, April 17–19, 1895, Savannah, Ga.; Medical and Chirurgical Faculty of Maryland, April 23, 1895, Baltimore, Md. ; Texas State Medical Society, April 23, 1895, Dallas, Tex.; South Carolina Medical Association, April 24, 1895, Columbia, S. C.

The New Examiner in Lunacy at Bellevue Hospital.—Dr. Alexander Trautman has been appointed a public examiner in lunacy at Bellevue Hospital, in place of the late Dr. Matthew D. Field. For a number of years he was one of the resident staff at the city asylum on Ward's Island.

The Late Dujardin-Beaumetz.—The friends and pupils propose to place a marble bust of the late Professor Beaumetz in the Hôpital Cochin, where so much of his work was done.

Alleged Death from Antitoxin.—A girl aged seventeen, living in Brooklyn, died apparently from the effects of an injection of antitoxin administered by her physician. The patient was suffering from diphtheria. Five minutes after injecting the serum, she had a convulsion, and five minutes later she was dead. The serum used is said to have been the Behring, and was imported. The autopsy proved that antitoxin was not the cause of death.

Oregon's New Medical Law.—Oregon can now boast of a law which places this State abreast of its neighbors regarding the qualifications required of practitioners coming into the State to begin the practice of medicine.

A Hospital Car has been built for the Savannah Florida, & Western Railway. The car has a wide door at the side for the admission of patients ; it is provided with a properly equipped operating-room and accommodations for the patients. This road is the first to equip and put into service a hospital car.

A Free Clinic for Electro-Therapeutics has been opened at 327 East Twenty-fifth Street by Dr. M. A. Cleaves.

The State Medical Library.—The supply bill appropriates $5,000 for the medical library.

The Epileptic Colony has the sum of $14,000 appropriated for its use the coming year.

Reviews and Notices.

THE RETROSPECT OF MEDICINE. A Half-yearly Journal Containing a Retrospective View of Every Discovery and Practical Improvement in the Medical Sciences. Edited by JAMES BRAITHWAITE, M.D., London, Obstetric Physician and Surgeon to the Leeds General Infirmary; late Lecturer on Diseases of Women and Children, Leeds School of Medicine, etc. Vol. CX., July–December, 1894. Issued January, 1895. London: Simpkin, Marshall, Hamilton, Kent & Co., Limited.

THE Retrospect differs from all other medical journals, and in many respects the difference is to the advantage of the Retrospect. It contains no news, no letters to the editor, no original articles, and comes out only once in six months. But when it comes it comes as a neatly bound volume, and the series in time makes a valuable addition to the library.

Of course the whole of medical literature cannot be summarized, but the selections in the subdivisions under General Medicine, Surgery, Obstetrics, and Gynecology have been made with skilful care.

TRANSACTIONS OF THE AMERICAN DERMATOLOGICAL ASSOCIATION, at its Eighteenth Annual Meeting, held at the Arlington Hotel, Washington, D. C., May 29, 30, 31, and June 1, 1894, in connection with the Congress of American Physicians and Surgeons. Official report of the proceedings. By CHARLES WARRENNE ALLEN, M.D., Secretary. New York: Press of George L. Goodman & Co.

THE present report is a credit to American dermatology. The average of the dozen papers is high. The discussions, though not extendedly reported, are pertinent. The illustrations, which are numerous and include several colored pictures, add much to the general good appearance of the volume, which, so far as we recall, is the most attractive one the Association has yet issued. The illustrations of microscopical sections are especially commendable.

A PRACTICAL MANUAL OF MENTAL MEDICINE. By DR. E. RÉGIS, formerly Chief of Clinique of Mental Diseases, Faculty of Medicine, Paris, etc. With a Preface by M. BENJAMIN BALL. Second Edition. Authorized Translation by H. M. BANNISTER, A.M., M.D., Utica, N. Y. Press of the American Journal of Insanity. 1894.

THIS interesting and valuable work on insanity received the Chateauvillard prize in 1886. Part first is devoted to mental pathology, general and special, and to the historical exposition of mental disease. Part second deals with the practical applications of mental pathology, preventive treatment, and curative treatment; and with medico-mental deontology, medico-legal practice, and medico-legal expertism. Régis's classification has much to recommend it, as only absolutely primary conditions are retained. Secondary states are ranked apart. These are morbid associations composed of two elements: (1) a vesanic element represented by any variety whatever of primary alienation (usually mania or melancholia), always identical fundamentally with itself; (2) a physiological or pathological element that serves, so to speak, as a substratum and varies according to the case. The first great division or class of mental diseases comprises functional alienations, and includes insanities, vesanias, psychoses. These are generalized or symptomatic (mania, melancholia, insanity of double form), or partial or essential (systematized progressive insanity). The second great division contains constitutional alienations: degeneracies, deviations, mental infirmities. These are vices of organization or degeneracies of evolution and vices of disorganization. The vices of organization are disharmonies, neurasthenias, phrenasthenias, and monstrosities (imbecilities, idiocy, cretinism, myxœdema). The degeneracies of disorganization are the dementias. Each form of mental abnormity is graphically described, and its course and possible and probable termination made thoroughly plain. Statements in regard to treatment are of the utmost practical utility. The book is not particularly well translated, which does not materially lessen its value to one who is a thorough French scholar. To others, however, the literal rendering of French terms into English may often prove a stumbling-block and a barrier to a correct understanding of the text. In any form, Régis's work is an important addition to the literature of the subject of which it treats; and is, in fact as well as name, a practical manual of mental medicine.

ATLAS OF THE DISEASES OF THE SKIN. In a Series of Illustrations from Original Drawings with Descriptive Letterpress. By H. RADCLIFFE CROCKER, M.D., F.R.C.P., Physician to the Department for Diseases of the Skin, University College Hospital; formerly Physician to the East London Hospital for Children; Examiner in Medicine at Apothecaries' Hall, London. Edinburgh and London: Young J. Pentland. New York: Macmillan & Co.

DR. CROCKER has written an excellent text-book on dermatology, which is well known in this country, so that, while an elaborate atlas of colored plates comes to us here as something of a surprise, so quickly following upon those of several well-known New York specialists, we are prepared to look for work of a superior quality, and worthy of special recognition.

At best, an atlas can portray but a limited number of affections, and usually we must be satisfied with a picture of one of the varieties or phases which a given disease may be capable of assuming. In the same way the descriptive text, printed in large type, as it usually is, can in nowise take the place of a text-book chapter upon the same subject.

No claim to completeness is therefore made in such a work, we are sure, though there are no prefatory remarks to indicate the scope and aim of the one which now interests us. The forty-two plates which have appeared are contained in seven large fasciculi, but as they include numbers ranging as high as eighty-six, the intention may be to continue the series. The size of the plates is 17 × 22, while in the International and Morrow's Atlas they are 12 × 17. Differing from the latter, the venereal diseases are not included.

Fasc. I. begins with Plate II. of Erythema Multiforme, showing in three figures the tubercular and circinate forms. The next is Plate XLII., Fig. 1 being an excellent representation of dermatitis gangrænosa infantum with varicella, and Fig. 2 showing miliaria infantum. The next plate is one of Ichthyosis of the Trunk. That devoted to Xanthoma has four figures giving the plane variety, involving the lids, the linear form on the palms, the tuberous variety on the knee, and the congenital disease as affecting the abdomen. Lupus Vulgaris with Epithelioma, in the next plate, shows a case of rather severe nature involving nearly the whole face. In the last of this series scabies is shown in an infant, and upon the hand of an adult.

Fasc. II. contains also six plates, the first illustrating the early and late stages of Urticaria Papulosa, or what has also been called lichen urticatus. The lesions of the early stage, which are difficult to portray, have been well brought out by the artist.

Under Lupus Vulgaris, in the following plate, we find the variety with multiple foci fairly well represented. the early stage of nodular lupus vulgaris of the thigh which has to be accepted on trust, and papillomatous lupus of the buttock, in which the lesion is well painted, but modesty or other consideration has prevented the artist from drawing a buttock which would be recognized unless labelled. Scrofuloderma claims a

very beautiful plate, with excellent figures of lupus verrucosus and verruca necrogenica. Scarkeloid makes a very striking picture occupying the whole plate. Seborrhœic dermatitis is the title of Plate LXXX., showing a condition of the scalp and adjacent skin of forehead and neck which is named suborrhœa eczemaformis, and a second figure beautifully illustrating that distressing cleft or fissured eczema of the palm.

A second plate on the same subject, and an exceedingly well-executed one, shows a variety called "seborrhœa papulosa seu lichenoides."

Fasc. III. opens with a very pleasing plate of four figures on Lichen Planus, including the disease as it affects the tongue. The "Bullous Iodide Eruption" of the face in the next full-sized plate shows lesions more resembling the solid tuberous growths which might follow the bullæ than the bullæ themselves.

Arsenical Pigmentation and Ulceration of the Abdomen and Keralosis of the Hand and Foot are well shown. In the plate on Verruca, the common wart and the flat wart are, according to the text, both meant to be represented, but one gets a strong conviction that the boy really suffers from molluscum contagiosum.

In the accompanying figure of Verruca Senilis the illusion would have been heightened had the skin on which the warts are painted been made senile as well. Lupus Erythematosus Sebaceus and Acne Varioliformis are each given a plate.

Fasc. IV. contains an excellent picture of Pemphigus with Bullæ, in which one can almost see the serum. The two varieties of Leprosy are also well depicted.

Fasc. V. has for its first plate Pemphigus Foliaceus, which is strikingly realistic even to the changes in the finger-nails.

Pityriasis Rosea is a disease very difficult to reproduce with the brush, but the attempt in this case deserves praise. Ichthyosis Hystrix Unilateralis is a rare condition, and in the very beautiful painting showing such an instance (which, however, isn't strictly unilateral) the artist has succeeded admirably. Circumscribed Scleroderma is well shown in two figures. The next plate shows in a striking way an extensive papillary pigmented Mole of the Arm, and a convoluted unpigmented Mole in a Child's face. Tinea Tonsurans is fairly well shown in three figures.

The best plate of the next fasciculus is entitled Hydroa Herpetiforme, commonly called on this side Dermatitis Herpetiformis, or Duhring's Disease. At last we come to Eczema—of which multiform disease two examples are given—and we pause to wonder whether the atlas would not be more useful to the general practitioner, if devoted entirely to the many varieties of this one disease. But then it probably was not produced for the general practitioner alone, and at any rate he would probably rather see Xeroderma Pigmentosum in a book than never see it at all.

Fasc. VII.—Prurigo of medium severity, beginning in a boy of seven, is shown in Plate VII. Impetigo Contagiosa and Ecthyma make good pictures, and give an excellent idea of the lesions as met with in cases of moderate degree.

The terrible but fortunately rare form of Pemphigus designated as Vegetans, is illustrated in a well-made painting from a fatal case of which a long description is given in the text.

Psoriasis Gyrata makes a pretty picture, but the actual lesions do not differ enough from some in the Psoriasis of Plate XXIII., considering the many clinical forms which the disease may assume. Elephantiasis Tropica is illustrated by an amputated leg, which gives too hopeless an impression of therapeutic measures in this formidable affection. We like better Dr. Aranjo's "before and after treatment" pictures of Elephantiasis. They are more cheerful.

Pigment anomalies complete the numbers to date. Chloasma Uterinum is well presented with lesions upon the forehead and regions of eyes and mouth.

As a whole the plates are meritorious, the drawing and coloring being, with few exceptions, executed with much skill. The lithographic and press work is truly praiseworthy, the text being printed upon sheets almost as heavy as are the plates.

The work bears the imprint of much care upon the author's part; the cases are personal and, so far as one may judge, the atlas contains no reproductions from previous publications. It sells at $6 a number.

First Aid to the Injured and Management of the Sick. An Ambulance Hand-book and Elementary Manual of Nursing for Volunteer Bearers and Others. By John Lawless, M.D., D.P.H., Surgeon-Captain, 4th V. B., East Surrey Regiment. Illustrated with forty-nine engravings. Philadelphia: J. B. Lippincott Co. 1894.

Part I. is divided into twelve outline lessons in first aid to the injured. Part II. is devoted to nursing, field hospital organization, the elementary principles of health, of diet for the sick, etc. An appendix gives a table of poisons, bearer's form of report for the medical officer, and a chapter on miscellaneous matters, as ventilation, disinfectants, medicines, and apparatus. The book compares favorably with earlier manuals and with those written by careful Americans.

Prescribing and Treatment in the Diseases of Infants and Children. By Philip E. Muskett, late Surgeon to the Sydney Hospital, etc. Third Edition, revised, enlarged, and rearranged. Edinburgh and London: Young J. Pentland. 1894.

The proportions of this little book are delightful: six inches long, three and a half wide, and about an inch thick. It slips easily into a physician's bag or pocket, and contains about 334 pages of concise and well-arranged matter that is valuable and practical. Its excellence is surprising throughout, even to the admirable index that adds materially to its usefulness. Drugs and applied therapeutics have received the most careful attention, and nothing seems to have been forgotten. The specialist will find the book helpful and suggestive, and so also will the general practitioner. It commends itself to the medical public.

Prostitutes and Pus-tubes.—It is very widely maintained among gynecologists that tubal abscesses are in a large measure traceable to the existence of previous gonorrhœa on the part of the husband. It is not uncommon for surgeons to contend that this condition is to be traced back to gonorrhœas that have passed away years before marriage. They insist that the gonococcus has been hiding away all that time in some quiet receptacle, only to come out and in the light of the honeymoon invade the uterus and tubes of the unsuspecting bride. If this contention be true, prostitutes who ply their trade more than two or three years ought not to possess healthy ovaries, for it is the rarest thing for them to escape having in that time two or more attacks of gonorrhœa. Yet, as far as impressions from our reading and personal observations go, they are strong that the number of operations on account of salpingitis among prostitutes is disproportionately small; and this, notwithstanding the fact that the temptation is great for those who would gain experience to operate on this class of patients. It would be interesting to know what proportion of cases of pus-tubes are found respectively in chaste women and in prostitutes.

It Has Been Proposed in England to make butchers and fishmongers pass an examination in the use of the microscope before being granted a license.

Vienna has had no cases of small-pox among its residents for nearly a year.

Society Reports.

NEW YORK ACADEDY OF MEDICINE.

Stated Meeting, March 21, 1895.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Would Separate Dependents and Delinquents in the City Hospitals.—DR. SEABROOK stated that at a special meeting of physicians held at the Academy on the 18th instant, it was voted as the sense of the meeting that many of the acknowledged evils connected with the City Departments of Charities and Correction would be done away with by completely separating the dependents from the delinquents.

On motion of DR. A. JACOBI the President appointed the following committee to consider the question involved in the communication: Drs. Jacobi, Janeway, Lusk, Morrow, and A. A. Smith.

Thanks Extended the Committee on Nurses' Bureau.—DR. R. H. SAYRE offered the following resolution, which was seconded by DR. JACOBI:

"*Resolved*, That the sincere thanks of the fellows of the Academy be and are hereby extended to the members of the committee on the organization and establishment of the Bureau for Nurses on account of the assiduity and good judgment displayed by them in their labors." Adopted unanimously.

The Coming Memorial Services on the Late Dr. Loomis.—DR. POLK reported for the special committee that Chancellor McCracken, of the University, and Dr. L. A. Stimson would speak at the memorial services on the late Dr. A. L. Loomis, to take place, as the President announced afterward, at the meeting on the first Thursday in June.

Diseases of the Eye Dependent on the Grip.—DR. THOMAS R. POOLEY read a paper on this subject. Grip, he said, might be defined briefly as a specific, epidemic, self-limited febrile disease, probably dependent upon a bacillus or microbe. In fact we might divide all acute epidemic contagious diseases into those in which the bacillus responsible for their existence had been found, and those in which it had not yet been found. Up to the present the bacillus of grip had not been definitely settled. Early in January of this year the disease had been very prevalent in New York, and there were still a few cases. In London and Berlin it was at present wide-spread and the mortality was great.

Dr. Pooley had participated in a grip symposium before one of our local medical societies in 1891, but in the five minutes allotted to him he had found it impossible to even enumerate the diseases of the eye which had been ascribed to it. In the present paper he would enumerate the affections of the eye which had been ascribed to the grip, and consider the grounds for the etiological classification. In doing this Dr. Pooley quoted cases from various authorities on eye diseases. While he seemed disposed to accept with some caution the assumption in some instances that grip was the origin of the difficulty, yet there were few diseases of the eye which had not now and then been traced back to this as apparently the only cause. It was especially necessary, however, to exclude other causes, such as tobacco, alcohol, syphilis, etc. The following conclusions were reached:

1. That eye complications following grip are comparatively rare, a fact which becomes apparent when we remember the immense number of cases of grip which have occurred during the past five years and the exceedingly small number of eye troubles reported as dependent thereon. 2. Many cases reported as due to grip are fanciful and need more substantial proof. 3. Grip may affect the eye directly, through inflammatory process, or through the accessory sinuses, or through the nerves. Inflammatory affections may involve the conjunctiva, the uveal tract, the tissues of the orbit, perhaps the fibrous capsule of tenon. 4. In some of these cases the extension is by continuity, and in others by metastatic or embolic process. 5. The nervous apparatus of the eye is especially liable to become involved, manifesting itself in paresis or paralysis of the intrinsic or extrinsic muscles, by papillitis, retrobulbar neuritis, and anæsthesia of the cornea. 6. Before assigning grip as the cause of any of the eye complications enumerated, careful scrutiny is necessary to exclude other causes, especially any affections of the nervous system, such as syphilis, tobacco, alcohol, and strain.

Diseases of the Ear Dependent on the Grip.—DR. EDWARD B. DENCH read the paper. In considering the subject of diseases of the ear dependent upon grip we had first to remember that epidemic influenza, like other acute infectious diseases, had constitutional symptoms which in their influence upon special organs acted as in other acute infectious troubles. Where the ear was involved it became a question whether it was through the action of the specific germ or toxines of the blood, or by these rendering the ear more vulnerable to other germs which might be present. The author had found it desirable for convenience to separate the cases in which grip affected the ear into those involving the external ear, the middle ear and tube, and the labyrinth and nerve.

Affections of the external canal could be explained by the presence of congestion, rendering the tissues susceptible to any germs present. The complications of greatest importance, however, involved the middle ear and Eustachian tube, just as was true in many other inflammatory conditions of the upper air-passages. There might be simple closure of the Eustachian tube on the one hand, or the other extreme of suppurative otitis media with mastoid involvement. The author laid stress on the importance of anticipating perforation of the drum membrane by incision, and thus obviate extension of the infusion, a change of its character to a more purulent form, and a ragged opening. Wherever incision had been performed the discharge seldom lasted more than a few days, while after spontaneous rupture it had been more profuse and long-continued. The ear should be kept clean by irrigation twice a day. Where the mastoid was involved by extension, the early application of cold might abort the inflammation. Politzer claimed that the superficial cells were more frequently involved, and deemed it unnecessary to enter the antrum, limiting his operation to the superficial cells, but Dr. Dench had not had such experience, and had found it necessary to do as radical an operation as in other cases of mastoid empyema. It was useless, he thought, to continue cold applications longer than forty-eight hours with a view to abort suppuration.

DR. C. S. BULL had found diseases of the eye dependent upon grip to be rare, yet a brief paper which he read contained histories of a number of cases from his own practice and that of others. A striking one of his own was a case of suppurative choroiditis, which was interesting because of its severity and fatal termination. The eye had been blind many years. The patient had grip in January. The eye began to swell and protrude, and by the fifth day was outside the socket. Treatment was continued three weeks before panophthalmitis and cellulitis subsided. After pus had discharged and the cellulitis had subsided, he removed the eyeball. There was a healthy appearance at the base, yet the patient soon developed symptoms of meningitis, and died of that affection, purulent form, as shown by autopsy. It was supposed that meningeal infection had occurred prior to enucleation of the eye.

In cases involving the nervous power of the eye the cause seemed to be a toxic agent, as they resembled cases of diphtheritic paralysis. There seemed to be two classes: the first in which the eye disease came on

during the attack of grip, the second afterward, perhaps several weeks afterward. The latter left more disastrous results as to vision, for there was not only inflammation of the sheath of the nerve, but also an acute degeneration of the nerve-fibres. He had had under his care since December 1st three cases of retro-bulbar neuritis and one of papillitis, with very numerous and large retinal hemorrhages. The latter patient regained his sight completely. The three patients with retro-bulbar neuritis had regained their vision for form, but the color scotoma had remained permanent.

Dr. J. H. Claiborne had seen but one case of eye disease which he could attribute to the influenza, a case of catarrhal conjunctivitis. The paper by Dr. Pooley had freed him of some scepticism as to the etiological relation of grip to diseases of the eye.

Dr. J. H. Weeks quoted from his paper on the subject under discussion, read in May, 1891, in which he had related a case of retro-bulbar neuritis in his own practice, and had collated fifteen more, and could now add four more cases where other causes than grip could be excluded. A synopsis of the four cases was given. Eye complications of grip were not frequent.

Dr. H. S. Oppenheimer made some remarks upon one point, namely, that lesions of the eye from grip might be of one eye or of both. He thought the severest cases of suppuration into the orbit and capsule had been bilateral, yet it appeared that a preponderatingly large number of all cases were in one eye only. He had furnished Dr. Pooley three cases to embody in his paper.

Dr. W. B. Marple said he had seen only one case in which he had not been able to find any other plausible cause for the condition of the eye than grip, a case of paralysis of accommodation, which had not yet been recovered from.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, March 18, 1895.

Samuel B. W. McLeod, M.D., President, in the Chair.

Syphilis of the Eye and its Appendages.—Dr. H. S. Oppenheimer read the paper. He said there was so great an amount of material relating to syphilis of the eye that he had found difficulty in selecting from it discriminatingly and in restraining himself from using too much. He had tried, however, to give a general glance at the subject, passing over most lightly the part which related to the pathology, as it was that of syphilis elsewhere in the system. Syphilis had been found to affect almost every portion of the eye. As six different cranial nerves supplied the eye or its appendages with nerve stimulus, it was very evident that syphilis of various portions of the brain might show itself here.

To begin with the lids, the primary sore was sometimes seen here, nor was this to be wondered at in view of the habit of rubbing the eyes with the fingers. The right eye was most frequently affected. The author had reported one case in which the source was said to have been a kiss. There was great swelling, coming on rapidly, and the chancre was slow to heal. In most of the reported cases the diagnosis had been made tentatively until the secondary manifestations had confirmed it. Gummatous infiltration of the skin and tarsus were also found, and resembled greatly primary chancre. There also appeared on the lids ulcerating papules or tubercles which in elderly persons were easily mistaken for ophthalmia, but they yielded readily to antisyphilitic treatment. When there was a history of syphilis it was easy enough to make the diagnosis, but without it we might have to resort to the microscope. The periosteum and tear-ducts were especially liable to be affected, and when the cause of obstruction to the flow of the tears was dead bone the prognosis was not so favorable. The lachrymal gland was rarely affected. There were sometimes papules on the conjunctiva, usually on the lid surface, but they had also been observed on the globe. The mucous patch sometimes appeared there. It ulcerated readily in this situation, and might be mistaken for primary chancre. Gumma sometimes appeared on the conjunctiva. Syphilis of the cornea unaccompanied by some complication was rare. Gumma of the cornea had been described. Keratitis dependent on congenital syphilis was not at all rare. It might cause a grayish haze or film in the cornea, in the midst of which were at times spots of denser gray or dirty white. It might spread over the entire cornea. The sclerotic border might be much or little injected; there might be vascular keratitis. Parenchymatous keratitis of congenital origin was frequently accompanied by Hutchinsonian teeth, but there were many exceptions. The most frequent age of the appearance of the keratitis was puberty, and it was often the first symptom of congenital syphilis. Often there were associated conditions, such as sunken nose, difficult hearing, cicatrices around the lips, joint troubles which were apt to be mistaken for rheumatism. Dr. Oppenheimer thought the changes in the cartilages and elsewhere were probably similar to those in the cornea. Two cases were cited in which antisyphilitic treatment directed against the parenchymatous keratitis caused the knee trouble to disappear as well.

The uveal tract, by which he meant the iris, ciliary body, and choroid, was most often affected in syphilis. One author had stated that forty-one per cent. of all the cases of iritis were syphilitic, and others had placed the percentage at from one-fourth to three-fourths. There was no distinguishing characteristic of syphilitic iritis unless there was a gummatous nodule; the diagnosis was based on corroborative evidence. It was not safe to trust to a negative history. The pupil should be dilated as soon as possible after iritis had been recognized. There were all grades of plastic iritis. In the more severe cases the pupils would become choked with the exudation in spite of all one's efforts, and end with closure of the pupillary space by dense matted tissue. In some cases there was finally glaucoma, or the disease travelled backward and involved the nerve.

Gummatous tumors could hardly be mistaken for other lesions. They were usually situated at the pupillary edge, but might be at the periphery, involve the choroid, etc.

Ophthalmoscopic examination often furnished valuable aid in the diagnosis of brain lesions. Aside from optic neuritis, there might be an affection of the other nerves supplying the eye, manifested by paresis, etc. While there was no single muscle, or combination of muscles, but what were affected occasionally, yet the paralysis usually involved the oculo-motorius (three-fourths of the cases), the abducens next, the trochlearis next. The intrinsic muscles of the eye were also not infrequently affected. Hemianopsia, aphasia, and Jacksonian epilepsy were often accompanying symptoms.

The author showed two pictures of syphilitic hemorrhage into the retina in young subjects. While the gummatous products might disappear entirely under treatment, arterial changes did so only partially, and the disturbance of nutrition caused by them might produce, years afterward, certain trophic changes, especially in the nervous system. Tabes, for instance; while it might not be exactly syphilitic, yet it was found almost exclusively in those who had been syphilitic. One of the plates showed thickening of the coats of the vessel at the fundus of the eye, which was likely to go on to closure of the lumen and, eventually, contraction of the vessel.

Dr. J. W. S. Gouley remarked concerning congenital syphilitic keratitis that he thought it implied syphi-

lis in the mother; it was not sufficient for the father alone to have had syphilis. It was rare that the cases were seen in their inception. He thought there was a tendency to meddlesome treatment in syphilitic iritis, while the very important indication to produce dilatation of the pupil was apt to be neglected and prove fatal to the iris. He believed in vigorous constitutional treatment.

Dr. J. R. Macgregor thought the comparative frequency of chancre of the eye in children could be accounted for by the delicate structure of their mucous membrane and skin, and by their rubbing the eyes with the fingers, which were not, as a rule, very clean. The irregularity of the surface of the cornea, and the streaky, spotted condition which was left where the deposit was not entirely absorbed, became very important diagnostic marks of previous keratitis originating in congenital syphilis. Dr. Macgregor thought the modern treatment of syphilis by very large doses of iodide of potassium started from Dr. William Kelly, who instituted it at Blackwell's Island about forty years ago.

Dr. Leonard Landes presented a man who had passed through a protracted and dangerous illness attributed to abscess of the liver which had existed a year.

Papers were read by Drs. J. W. Gleitsmann and Carl von Ruck on the "Modern Treatment of Laryngeal and Pulmonary Tuberculosis." (See p. 424.)

Dr. F. J. Quinlan said that one of the most prominent symptoms in laryngeal phthisis was pain, and nothing gave more relief from this than cocaine. A fifteen or twenty per cent. solution touched over the parts would enable the patient to take nourishment. Lactic acid could be regarded as almost a specific in ulcerations of the larnyx. Creosote might be used internally or locally after the method of Chappell, but European observers had spoken of a depressing effect resulting from deluging the patient with creosote, which was regarded as worse than the disease itself. While the surgical procedures might seem heroic, he had no doubt that in judicious hands they would be of great value.

Speaking of prophylaxis, Dr. Quinlan emphasized the need of attention to the nose. This was regarded to-day as an essential to healthy lung action; the contraction and dilatation of the vessels in the nasal passages was similar to that going on in the air-cells of the lungs. All irregularities of the nose should be corrected, as the primary step toward healthy lungs was proper inspiration. To breathe through the mouth, or to have air enter the lungs over diseased nasal passages would expose to infection any broken surface below.

Dr. Chappell, to whose paper reference had been made by Dr. Gleitsmann, described his method of injecting creosote beneath the mucous membrane in laryngeal tubercular infiltration. As a spray he used a mixture composed of one drachm of creosote to one ounce of castor-oil, and for injection into the mucous membrane one composed of two drachms of creosote to one ounce of castor-oil. The injection relieved pain and cough, and promoted resolution without destroying the superficial epithelium of the larynx, which was important in order to obviate further infection.

French Population Statistics.—During the year 1893 were registered 287,294 marriages, 6,184 divorces, 874,672 births, and 867,526 deaths. The increase of births over deaths was 7,146 (the population of England, with nine millions less, increased during the same period by over 500,000). The percentage of marriages was 0.7, of births, 2.29, and of deaths, 2.28. The total number of illegitimate children was 70,562, which is the highest figure yet reached, and represents 8.8 per cent. of the natality.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DEATHS OF SIR W. SAVORY, BART., F.R.S., DR. HACK TUKE, MR. CHANCE, F.R.C.S., MR. HIGGINBOTTOM, AND DR. C. E. ARMAND SEMPLE—THE EPIDEMIC OF INFLUENZA—INCREASED MORTALITY—MEDICAL SOCIETIES—HYSTERICAL DEAFNESS—FLOATING KIDNEY—OBSTETRICAL SOCIETY'S ANNUAL MEETING—EFFECT OF HIGH-TENSION CURRENTS—CLINICAL SOCIETY—CEREBRAL TUMORS—DIABETES AND PSORIASIS—RUPTURE OF GALL-BLADDER—CYSTIC SARCOMA—ARREST OF DEVELOPMENT.

London, March 9, 1895.

Disease and death constantly occupy the attention of the profession. This week they come home to us with unusual force, for death has laid his hand heavily on London doctors, and influenza has maintained its hold on the community. To begin with the notable deaths among us. No sooner is Mr. Hulke, the president of the College of Surgeons, laid in his grave, than Sir William Savory, a distinguished predecessor in that office, is seized with his fatal illness. Sir William Scovell Savory, F.R.S., was born November 30, 1826, and died on March 4th. After school-days, he became a student at St. Bartholomew's Hospital, with which he remained connected throughout his life—passing regularly through the stages on the surgical staff, until on resigning he was elected consulting surgeon (1891). In 1848 he graduated at the London University and obtained the great distinction of "University Medical Scholar." In 1852, he took the fellowship of the College of Surgeons. In 1870, he became an examiner; in 1877, a councillor; in 1885, president, and was re-elected in 1886, 1887, and 1888—a record at the college.

It was during his presidency that great meetings of members and fellows were held to claim the right to some influence in its government. Savory was opposed to the claims, and no doubt his re-election was due to the knowledge of the council that he was the strongest man of their party to put forward, and he certainly led the forces of resistance with consummate skill. At the same time his courtesy and forbearance in the chair as the representative of the few in face of numerous hostile audiences, elicited the acknowledgment that he was fair and considerate.

As a surgeon, his position at St. Bartholomew's may speak. He held that position with honor for the full period. At the clinical consultations no opinion was more influential, and in private practice no surgeon's help was more valued by practitioners.

But perhaps it was as a teacher that his influence was greatest. He was one of the most eloquent of our leaders, and his lecture-room was crowded with earnest pupils, among whom were often listeners who were already in practice.

As an examiner he was rather dreaded, and at one time had an unenviable reputation for severity. This was perhaps due to impatience of ignorance in candidates of elementary facts, or of matters which endangered life. But to the nervous man he was considerate, and would take trouble to reassure him and to find out if he knew the subject. His baronetcy, conferred in 1890, descends to his only son, a clergyman.

Dr. Hack Tuke died on Tuesday (5th). His name will be well known to your readers as an authority on insanity, a subject which was his by inheritance, for from the time of his great-grandfather the Tukes have followed this branch of medicine. He was born in 1827, and in 1858 was joint author with Dr. Bucknill of the "Manual of Psychological Medicine," which has maintained so high a place. He was for nearly twenty years editor of the *Journal of Mental Science*,

and his important "Psychological Medicine" came out in 1892. He was president of the Medico-Pyschological Association, which owes much of its success to his influence. He filled a great position in the profession with honor to himself.

Mr. E. J. Chance, consulting surgeon to the Metropolitan Hospital, died last week at the ripe age of eighty-eight years. He became a member of the College of Surgeons in 1835, and a fellow in 1843. It seems like turning to long-past institutions to say he was a lecturer in the Aldersgate and Hunterian schools of medicine. He was for many years surgeon to the City Orthopædic Hospital, and had previously held the assistant surgeoncy at both the other orthopædic hospitals—the National and the Royal.

Marshall Hall Higginbottom, of Nottingham, died on the 24th ult. He was the son of John Higginbottom, F.R.S., who also practised at Nottingham, and will be remembered as the originator of the treatment of erysipelas by surrounding it with silver nitrate. He was also a great teetotaller at the time when temperance views were in such a minority that he seemed almost to stand alone against the rest of the profession. Could he have seen what his son lived to see! This son was named after Dr. Marshall Hall, who was his uncle. He qualified in 1844, and joined his father in practice at Nottingham.

Dr. C. E. Armand Semple died on Tuesday last, aged fifty. He was secretary to the Board of Examiners of the Apothecaries' Society, and had previously been a medical tutor and compiler of several student's "aids." He was also physician to a Children's Hospital and to the Royal Society of Musicians.

Enough of deaths for one week. As to disease, influenza still reigns. Last week its mortality rose to 296 from 111 the week before. In the 1893 epidemic the highest weekly number was 164, so we are already far ahead of that. The only set-off is that diphtheria still declines and small-pox is diminishing, not only in London, but in most provincial towns.

London, March 16, 1895.

Influenza is still uppermost in our talk. An official memorandum has been issued by the Local Government Board, in consequence apparently of the question asked in Parliament. It may serve to urge people to go to bed and nurse themselves early in the attack. Of the six outbreaks since 1889–1890, this seems the most sudden and is certainly the most fatal. The mortality has again risen. From the returns to March 2d, which I have reported as two hundred and ninety-six deaths in the week, the number rose last week to four hundred and seventy-three, and the deaths from all diseases of the respiratory system also rose. The epidemic probably has passed its highest, for it must be remembered that the registration returns are necessarily somewhat behind in point of time. As I anticipated, the provinces have been invaded in all directions, and the mortality has been great, so that even a healthy town like Brighton showed the high rate last week of 40.1 per 1,000 of population. In all sorts of assemblies vacant places may be noted, not only of those who have died, but of a much larger number who are attacked and are either in bed or confined to the house. An example of this was seen at the Medical Society's dinner on the 8th, when several expected fellows were absent, but a similar circumstance may be constantly met with even at private dinner-parties. If, as I surmise, the worst has passed, we shall soon return to our ordinary state, but many will be a long time before they feel strong again.

At the Medical Society on Monday last, Dr. Hector Mackenzie related a case of hysterical deafness in a girl aged sixteen, who two years before had had sore throat (diphtheria?) and then influenza; earache followed, for which she was politzerized, with the result of causing sharp pain and almost total deafness. Soon after anæsthesia and loss of muscular force came on, which ultimately became general; the ability to use her limbs was only regained by a tedious course of training, and even when she had recovered power over her legs, deafness remained; but this was restored by the re-education of the auditory centre.

Mr. Bruce Clarke gave an epitome of the results obtained by him in thirty operations undertaken for the relief of movable kidney. In several of the cases the condition of the kidney was such that it was thought best to remove it, and in several there was calculous deposit. Mr. Clarke regards this as secondary to the undue mobility of the kidney, which leads to retention of urine, dilatation of the organ, and liability to calculous deposit. Undue mobility of the kidney, he thinks, is a more important factor in the production of renal disease than is usually suspected, but data are still wanting on which to found any rule of practice. If floating kidney could be shown to lead, even in a moderate proportion of cases, to hydronephrosis, etc., additional weight would be given to the view of operating in all cases without waiting for the condition of the kidney to become such as to necessitate surgical intervention. In the discussion the necessity for operation in a large proportion of these cases was questioned, and the general opinion seemed to be that operation should be postponed until an attempt had been made to afford relief by the use of a belt or other appliance having for its object the partial immobilization of the wandering organ.

The Obstretical Society held its annual meeting on Wednesday (6th), when Dr. Champneys, the incoming President, delivered his inaugural address, which he devoted to the defence of the Society in issuing to midwives the certificates which have been condemned by the General Medical Council, and spoke of the nameless horrors that would be perpetrated if midwives were not examined. A copy of the address is to be sent to members of the General Medical Council, members of Parliament, and others, who may be interested in knowing the attitude of the Society in regard to the recent action of the General Medical Council in the matter of certificates to midwives.

Dr. J. Inglis Parsons read a paper on the "Disintegration of Organic Tissue by High-tension Currents," on which a discussion followed as to whether these effects were not due to heat, considerable differences of opinion being expressed.

At the Clinical Society, on Friday (8th), Dr. Handford read notes of a case of cerebral tumor in a man, aged forty-three, who had been injured by falling out of a cart upon his head. A fortnight afterward he became mentally depressed, and experienced gradually increasing failure of power, and later serious symptoms supervened resembling a previous case recorded in *Brain*, 1891. A diagnosis was made of tumor, probably sarcoma, arising in the injured tissues and situated on the right side close to the motor tract. The patient was trephined, but the tumor was not found, and at the necropsy shortly afterward a tumor was discovered, four inches by seven and a half inches in size, firm in consistence and dark in color, situate behind and to the outer side of the right corpus striatum. Microscopically it was a vascular sarcoma, containing some spindle cells and in places a coarse meshwork filled with uninjured blood-corpuscles. Dr. Handford expressed the opinion that the causal relation between the injury and the new growth was undoubted in each case, and that the frequency of such occurrences was somewhat underestimated. Several speakers mentioned similar cases in which the symptoms had more or less continuously progressed from the time of injury.

Dr. Grube, of Neuenahr, reported four cases illustrating the association of diabetes with psoriasis. He thinks this association is not a mere coincidence.

Mr. Arbuthnot Lane read the notes of a case of rupt-

ure of a gall-bladder and liver produced by violent straining in a woman, aged fifty-four, suffering from obstructive jaundice of about three or four months' duration. The greatly distended gall-bladder was exposed, the tumor at once projecting through the incision. It was incised and more than three-fourths of a pint of blood-clot was removed. As it was then found that the common bile and common hepatic ducts were enormously distended by the same material, nothing further was done. Dr. Shaw examined the parts, and found that the hepatic aspect of the gall-bladder, together with the adjacent portion of the liver, were rent, and that all the ducts in the liver also were filled with clot. In support of his explanation that the rupture had resulted during violent straining, Mr. Lane quoted from a paper by Dr. Willard, in the "Transactions of the American Surgical Association, 1893," a case in which death appeared to have resulted from rupture of a distended gall-bladder and from hemorrhage into the peritoneal cavity.

Mr. Spencer showed a specimen of traumatic cystic lympho-sarcoma of five years' growth. The right upper extremity was removed, and owing to the skin being widely involved the whole of the wound had to be covered in by a flap from the upper half of the arm. The gentleman is about to return to New Zealand, the prognosis seeming to be favorable.

Dr. Wallis Ord related a case of unilateral arrest of development with arcus senilis and without hemiplegia in a girl, aged twelve, but suggested that it was a very mild form of infantile spastic hemiplegia, though no spasm was present.

THE STATE AND THE DRUG-STORE.

To the Editor of the Medical Record.

Sir: It appears to me that, in your editorial comments on "The State and the Drug-store," you have misapprehended the nature and the objects of the work which the board is doing in the matter of drug adulteration, and I therefore beg that you will allow me to make a brief statement concerning this work. During the last year, in addition to a large amount of other chemical work, 2,289 samples of drugs, collected from many hundreds of stores in sixty-three localities, were examined. Of this number 69.5 per cent. were of good or fair quality, while 30.5 per cent. were of inferior quality or materially varied from the pharmacopœial, which is the legal, standard. Of these latter samples very few were adulterated in the sense in which that word is ordinarily and popularly employed, that is, by the intentional addition of foreign matter with intent to cheapen the article, but under the law [1] a drug is adulterated "if when sold under or by a name recognized in the United States Pharmacopœia, it differs from the standard of strength, quality, or purity laid down therein." Therefore if a medicinal preparation is impure as a result of careless or improper manufacture, or has deteriorated from too long keeping or exposure, it is adulterated within the meaning of the act, and the retailer is responsible for its quality even if not prepared by him. Again, the pharmacist is often, in a sense, forced to dispense articles which are of inferior quality in response to the demands of the physician. For instance, many physicians insist that reduced iron shall be black, and if tablets are gray they return them, notwithstanding the fact that none of the "black irons" of the trade answer to the pharmacopœial requirement, and reduced iron which contains eighty per cent. of metallic iron is necessarily gray in color. Druggists as a class are, in my opinion, not less intelligent and honest than men engaged in other pursuits, and it is my belief that, for the most part, they desire to conduct an honorable business in an upright manner, but they often make mistakes, and they frequently dispense goods as they buy them without particular inquiry as to quality or the application of tests for strength and purity. A large proportion of the medicinal agents in which they deal are seldom or never adulterated or of inferior quality, and such articles we do not collect, as their examination would involve needless work with no good result, but we select such articles as are known to be often of inferior or inexact strength, or otherwise of inferior quality, or liable to deterioration through improper preparation or careless keeping, and for this reason, as stated in each of our reports, the percentages of good, fair, and inferior articles reported by no means represent the proportions of good, bad, and indifferent drugs on the market.

[1] Chapter 661, Laws of 1893, Article III.

The object of the work, as conducted, is not to determine the ratio of adulteration, as such an inquiry would have but little practical value, but to expose sophistication, substitution, adulteration, and carelessness in the preparation and sale of drugs and pharmacopœial preparations; to inform the public, and warn ignorant and careless dealers. In this direction we are working in common with the colleges and boards of pharmacy and the pharmaceutical associations and journals, but much more directly and effectively, since our printed reports disclose the name and place of business of all dealers from whom samples have been obtained, and the quality of the articles sold by them. Notices are promptly sent from the office of the board to all dealers whose samples have been found to be of inferior quality, enclosing a copy of the analyst's report, and warning them to desist from the sale of such articles, and in most instances these notifications are not only gratefully received, but as promptly complied with. For many reasons it is impossible in every instance to visit such dealers again within a definite period, but such second collections and examinations are made from time to time so far as it is practicable to do so.

Now, concerning the further treatment of dealers whose drugs have been found below standard quality, while the responsibility does not rest with me, I am decidedly of the opinion that a resort to extreme measures is seldom necessary or advisable. The warnings of the board are very generally respected, and I believe that the work which it has done has exercised a most important influence in improving the quality of the drugs sold in this State. That cases deserving of prosecution might be selected I am willing to admit, but in the great majority of instances gentler measures suffice, and, in my opinion, it would be unwise, inexpedient, and impolitic to resort to legal measures for the correction of such errors as are comparatively unimportant, and are often unintentionally committed. There is a sense, of course, in which all variations from strict accuracy in dispensing drugs are important, but we must recognize that some things are more important than others. If a druggist puts up strychnia for morphia, or sells laudanum for paregoric, or wilfully debases active and important remedies, such errors are of the first magnitude, but if he sells magnesium carbonate for magnesia, or safflower for saffron, no very great harm has resulted, and when he is informed of his error he will, in most cases, guard against it in the future. If, in such cases as these, legal proceedings were instituted, the expenses attending them would be disproportionate to the good accomplished; the business of reputable dealers might be ruined, and in conducting such a crusade I am convinced that we should not receive the sympathy or the support of the medical profession or the public at large.

In conclusion, it seems to me that the work in which the board is engaged is deserving of the support of such journals as the Medical Record rather than of ridicule based upon an imperfect knowledge of what this work really is. If, in the opinion of some, we have erred on the side of too great leniency it has been be-

cause of a desire to avoid harsh, arbitrary, or sensational methods in dealing with the pharmacists of our State, the great majority of whom are intelligent and honest men, who when they err do so more often through ignorance than deliberate intent. We have no desire to escape impartial criticism or just censure, but we ask that our work may be judged by our reports of it, which are "in evidence," having been before the public for years, rather than from hastily prepared and incomplete newspaper reports of legislative inquiries.

Willis G. Tucker,
Director State Board of Health Laboratory.

Albany, March 19, 1895.

FOREIGN BODIES IN THE APPENDIX.

To the Editor of the Medical Record.

Sir: In a recent number of the Medical Record a contributor states that the literature of foreign bodies in the appendix may be enriched. In a contemporary appears a note that the grape-seed which has caused appendicitis is yet to be found.

During the summer of 1883 I made an autopsy of the body of a well-developed male, who died, having all the symptoms of acute general peritonitis, after four days' illness. About the appendix was found two ounces of pus, in which was found two apple- or pear-seeds. In a perforation of the wall of the appendix was found a similar seed, one end of which projected into the cavity of the appendix, the other end projected into the peritoneal cavity. In the cavity of the appendix was a piece of hardened fæces one-half inch long and one-fourth inch in diameter. The appendix was four inches long and one inch in largest diameter. In the walls were three openings about one-eighth of an inch in diameter. These openings were as cleanly cut as if made with a hollow punch of the same diameter. Through these openings the seeds found in the pus evidently passed, as in one opening the seed was found lodged. I have this specimen in my possession, although the seeds were recently lost while changing the preserving fluid. This specimen was exhibited to the Cayuga County Medical Society. If the grape-seed has not been found, the apple- or pear-seed has.

Respectfully yours,
John W. Kales, M.D.

Franklinville, N. Y., March 19, 1895.

A NEW APPLICATION OF THE KERATOMETER OF JAVAL.

To the Editor of the Medical Record.

Sir: It may interest those of your readers who are using the keratometer to learn that there are other possibilities in its use besides that of measuring the curvature of the cornea.

While examining a patient's cornea and iris one day, with oblique illumination, the thought struck me that I might obtain equally as good, if not a better, view of these parts with a javal. Seating my patient before this instrument and lighting but one of the lamps, the light was made to fall directly upon the cornea. After a little manœuvring with the telescope a fairly good view of the iris was obtained. As soon as the iris came into the field the reflexes of the disk appeared. Further experimenting brought out the fact that to see these surfaces distinctly it was necessary to take the illumination from a little back, and to the same side as the eye to be examined, then focus the light upon the eye with a mirror of eleven-inch focus. I used a gas flame for illumination, and my head-mirror, which I held in my hand. The details of the cornea, if opacities are present are very distinctly seen; the color of the iris, its structure, the crypts, contraction furrows, pigment patches, and pupillary zone are all clearly brought out. Opacities on the anterior surface of the lens may be seen. The image thus obtained is magnified and all the details easily made out, such as tumors or synechia. By mounting the mirror on a stand both hands are free to make a sketch of the actual situation of adhesions.

While we are measuring the curvature of the cornea, it takes but a moment to carry out this examination, should it be thought best to examine the iris. If the patient will look through the opening in the disk, thus relaxing the accommodation, the pupil will dilate and uncover any adhesions of iris, should they be present.

A slight disadvantage in examination by this method is due to double images of the large disk and mires. By revolving the tube, the image caused by the prism, which lies just outside the optic axis of the tube, will be carried around the stationary image, thus all portions of the iris will be seen in turn.

W. F. Southard, M.D.

603 Sutter Street, San Francisco, Cal.

WARNING AGAINST CASTRATION FOR PROSTATIC ENLARGEMENT.

To the Editor of the Medical Record.

Sir: Permit me to call the attention of your readers to the "Warning against Castration for Prostatic Enlargement," by Dr. Belfield, of Chicago, which I hope will have a wide publicity through your columns.

It seems to me that this warning is timely, and I desire to express my agreement with the position taken by Dr. Belfield. In many of the cases of castration which have been appearing in the medical press, both foreign and domestic, there has been a very striking lack of proper observation of the cases prior to the operation, and an equally imperfect report of the patient's subsequent condition, nor do we know how many deaths have followed the operation. The relief to these patients, which in some of the cases was reported as appearing within a few hours after the operation, has been too positive to be attributed to the operation itself, for it hardly seems rational to believe that a hyperplastic organ, in which, no doubt, there has been an increase of the connective-tissue element, should diminish in size within a few hours after castration has been performed. It is within the experience of many surgeons to have seen an acute cystitis and inflammatory engorgement of the prostate rapidly subside under rest in bed and other equally simple measures. Moreover, as Dr. Belfield says, mistakes in diagnosis are very easily made unless complete exploration of the bladder and prostate is resorted to prior to the operation.

Let me also call attention to the difficulty of determining the size and relative diminution in size of the prostate by the ordinary methods of examination. It seems to me that in order to test the results of such an operation, which is based on theory alone, the size of the prostate should be determined by three examiners and the examinations repeated with sufficient frequency to determine positively the size of the organ.

The operation of castration for hypertrophied prostate does not prove anything unless it has been demonstrated in a given case that other measures which have hitherto given relief were employed and failed. Elderly men with enlarged prostate are always liable to acute exacerbations and inflammatory engorgement, ofttimes to such a degree that retention of urine will result, with over-distention and subsequent atony of the bladder. Many of these cases can be relieved without immediate catheterization by putting them to bed, thus reducing the volume of blood in the pelvis, and by hot irrigations, etc. Then, when instrumentation becomes justifiable, they regain a certain amount of spontaneous urination and have no more residual

urine than have many of the cases which have been reported as "cured" by castration.

A theoretical operation based upon observations upon dogs and eunuchs, in whom physiological atrophy of the prostate is said to be induced by the abrogation of its sexual function, cannot reasonably be applied with the expectation of getting the same results in elderly men in whose prostates hyperplasia has already taken place. If this theory could be proven, about one man in three after the age of fifty ought to submit to castration in order to prevent enlargement of his prostate. Respectfully yours,

L. Bolton Bangs, M.D.

New York, March 26, 1895.

INDECENT MEDICAL ADVERTISING.

To the Editor of the Medical Record.

Sir: I received to-day (in common with many other victims, I suppose) a pamphlet containing some twenty reproductions of photographs of syphilitic skin lesions. Many of the pictures were of men stark naked, and showing uncommonly well-developed genitalia. One picture showed the genitalia, and but little of the man.

This pamphlet, issued to advertise some proprietary nostrum, was sent by mail to my house and lay for a while on the table of my waiting-room, in an unsealed envelope, so that any woman or child prompted by curiosity might easily have inspected it—which they would have been all the more prone to do since the wrapper was marked in large letters, "For Medical Men Only."

While photographs of this kind have a legitimate place in systematic works on syphilis, to use them for purposes of commercial exploitation is disgusting; and to thrust them into a man's house in such a way that any member of his family—women and children and the female servants—may easily get hold of them, is a signal invasion of his rights.

I have sent the pamphlet with the wrapper, as I received it, to the Postmaster-General, at Washington, with the request that the Post-office take means for the abatement of this nuisance. For scarcely a week goes by without there arriving by mail, in open envelopes, pamphlets marked in large letters on the covers, "Painful Menstruation," "Sterility," "Impotence," or some such title calculated to arouse curiosity, and it is some trouble to be obliged to tear these into pieces small enough to be useless before throwing them into the waste-basket. But pamphlets of this sort are petty annoyances compared with the ostentatious indecency of the publication received to-day. While we may call on the postal authorities to protect us from having these things thrust into our houses in unsealed envelopes, yet the ultimate cure for this evil, steadily on the increase, must be sought in the attitude of the medical profession itself, which should mete out a stern disapproval to all who, for the sake of selling their wares, offend against decency and good sense.

Yours truly, Walter Mendelson, M.D.

159 West Seventy-fourth Street,
March 28, 1895.

The Physiological Effects of Cycling.—Dr. Blajevitch, of St. Petersburg, has published the results of his observations upon the physiological effects of cycling. These showed that the play of the chest immediately after riding diminishes from 1 to 1.5 ctm., especially in the cases of women and children, and of men racing or beginning to use the cycle. The general effect of a summer's riding on men was practically nil; in women and children the vital capacity was slightly increased. The arm power was found to have increased more than the leg power in young persons and in beginners, but in the case of mature men used to cycling this was not so evident.

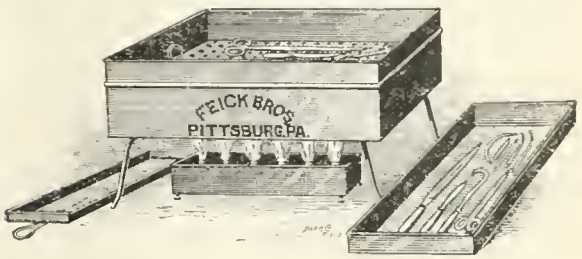
New Instruments.

A NEW PORTABLE STERILIZER.

By N. O. Werder, M.D.,

Pittsburgh, Pa.

The sterilizer has become almost inseparable from aseptic surgery, and is rarely absent from the modern operating-room. It has not found the general introduction into private practice which it deserves, and the surgeon frequently dispenses with its use during operations in private houses, often to the detriment of the patient, because those in general use are not well adapted for transportation, and even the few portable ones in the market are either not suitable for all operations or else too large and heavy, containing at the same time so many attachments that comparatively little room is left for the necessary instruments and dressings. No doubt many physicians have felt the want of a sterilizer which is compact and light, with sufficient space for all instruments and dressings, used in ordinary operations, including laparotomies, at a modern



price. The sterilizer herein described is believed to be one which is really "portable." It is 12 inches long, 6 wide, 3¾ high, with legs attached to the bottom of the apparatus, which can be folded up when not in use. It is made of copper with tin lining and nickel-plated inside and outside. Weight four and one-half pounds. The inside space is divided off into two compartments by a perforated tray of the same material, an upper one 2 inches deep and 12 inches long for dressings, etc., and a lower one 1¾ × 12 inches for the soda solution into which the instruments are placed. The cover or lid is 1 inch deep by 12 inches long, and is intended to be used during the operation as a tray for the instruments. It is large enough to hold all the instruments and sutures ordinarily used during an operation. It is heated by an alcohol lamp with four Bunsen burners, requiring about six ounces of alcohol to keep it boiling from twenty-five to thirty minutes. The inside perforated tray has heavy wire feet which can be folded, so that the whole space, 3½ × 12 inches, can be utilized for packing instruments, dressings, etc., quite sufficient for all ordinary operations. There is no necessity for carrying trays along, as the lid makes an excellent tray. The instrument is neat in appearance and can be carried in a canvas cover with straps, the whole apparatus when packed being 12¼ inches long, 6¼ wide, and 3⅞ high. In laparotomies, etc., in order not to fill up the space unnecessarily with thick, heavy towels, the author has been in the habit of using cheese-cloth, of which several yards are boiled with the instruments in the sterilizer; it takes up very little room, and at the same time answers the purposes just as well as towels.

A Line of Medical Ancestors.—William Hunter Baillie, who recently died in England at the age of ninety-eight years, was the only son of Matthew Baillie, M.D., who attended George III. during his frequent illnesses. His mother was one of the twin daughters of Thomas Denman, M.D., John and William Hunter were his great uncles, and Sir Benjamin Brodie was his first cousin once removed.

Speaking to the Eyes.—We hear, as a matter of fact, with that portion of the brain set apart for receiving impressions of sound, and not with the ears. For example, the appreciation one may have for music depends not on a musical ear, as it is called, but on a musical brain. So when the ears of a deaf person fail to pass sound along into the brain he may, notwithstanding, take cognizance of speech by seeing the expressions of one who in speaking makes certain motions with the lips, teeth, tongue, eyes—in fact with the entire face. A glance of the eyes, a smile or a frown, may be aided by a shrug of the shoulders or some motion of the hand. By such means may one convey their thoughts to a person deaf as a post. The *Tribune* of Sunday, March 24th, referring to this subject, tells how Miss L. E. Warren, of this city, has systematized this work, and gives instruction to classes of very deaf persons in expression reading. Miss Warren has a method which makes it quite easy to instruct the deaf to converse with others; it is similar to the well-known Bell method now used in educating deaf children. She finds that persons who have become deaf after receiving their education, however, are much more easily taught to see speech, so to speak, than one of those born deaf, and who have to be educated by this method at the same time. This is an entirely new field of work, and is somewhat like teaching a foreign tongue to persons obliged to live in a country where a strange language is spoken. There is said to be an amusing side to this accomplishment, for an adept in expression-reading when at a distance may understand from the motions of even a mustachoed lip the whispered words of a fond lover intended only for the fair one's ears, or the unspeakable gossip of the sex who chatter away without reserve. It is quite possible that it may soon become the fashionable vogue to acquire the art of conversing thus silently with your friend when in the midst of the noise of social life.

A Medical Circulating Library.—Dr. Marcel Beaudoin, General Secretary of the French Medical Press Association, has started a medical circulating library, organized on the model of the London circulating libraries. A subscription of 15s. a year entitles the subscriber to have forwarded to him all the books he may desire; the price of carriage is deducted from the deposit fee—5 francs (4s. 2d.) for each book asked for. Dr. Beaudoin has also organized the "Service des Fiches Bibliographiques." Instead of grouping facts and subjects in the order of their occurrence, they are grouped in the order of specific sequence. The subscription is 8s. a year, and each "fiche" costs one halfpenny. "A Fiche Analytique" is to be added to this organization, in which foreign works will be analyzed in the French language. After November, 1895, a reading-room will be attached to this circulating library.

Treatment of Lupus by Cantharidinates.—There was a large audience at a recent meeting of the Berlin Medizinische Gesellschaft to hear Professor O. Liebreich's paper on the treatment of lupus by cantharidin, and on tuberculosis. His theory of tuberculosis is briefly as follows: In the case of animals—for instance, of guinea-pigs—the smallest doses of tubercle bacilli suffice to create a general disease, which in every case kills the animal. But the resisting power of human beings is much greater. An inoculation of tubercle bacilli would, in a healthy individual, produce not general tuberculosis but only localized nodules. The disease could only supervene where there was what is called a predisposition—that is, diminished vital energy of the cells of the organism. The healthy human cell resists the action of parasites, and only where it is weakened can it be attacked by nosoparasites. In treating nosoparasitary diseases, it is important to strengthen the vitality of the cells, and Liebreich has found cantharidinate of soda or of potash most valuable for this purpose. A dose of 2 decimilligrammes may be taken for years without affecting the kidneys, and under the influence of the drug the lupus clears away uniformly. A patient of Liebreich's, completely cured of lupus of the face and arms, was shown. The discussion was adjourned till next meeting.—*British Medical Journal.*

Sterilization of Water.—M. Frémont has succeeded in proving experimentally that water maintained for twenty minutes at a temperature of 80° C. loses all the pathogenic micro-organisms it may have contained without being deprived of its gases and without involving any precipitation of the contained salts. It is stated that the flavor of the water is in nowise modified by the process—a most important consideration.

Which is, Ophthalmologically, the Best Artificial Light?—Dr. Trousseau, surgeon to the Quinze-Vingts Eye Hospital, gives the preference for innocuity to incandescent electric light, and assigns the second place to petroleum lamps, which may advantageously be employed for ordinary purposes. He condemns *in toto* the light yielded by oil, and more particularly that given by candles. The gas-jet is the most hurtful to the eye, its only recommendation being its convenience.

NOTES ON INTRA-VENOUS COAGULATION, WITH SPECIAL REFERENCE TO THROMBO-PHLEBITIS.[1]

BY W. GILMAN THOMPSON, M.D.,

NEW YORK.

I HAPPEN to have seen a much larger number of cases of phlebitis, or thrombo-phlebitis, within the past two or three years than before, and this I was at first inclined to attribute to the prevalence of the grip. However, upon analyzing them I was in doubt as to whether this was not merely a coincidence, for the theory of grip causation does not wholly account for the increase, although in the New York Hospital there were but two cases of primary thrombo-phlebitis treated in the year before the grip arrived, against seven last year.

I have tabulated 73 cases which are recorded as occurring at that institution in the fourteen years from 1880 to 1894. Prior to 1891 the number never rose above 7 cases per year, and that maximum was reached but once, and between 1891 and 1894 it rose from 2 to 24. This latter figure is out of all proportion to the increase in the general hospital service. The period which exhibits this striking increase in the number of cases is coincident with the prevalence of the grip, but I find only four cases in which that disease is mentioned as occurring simultaneously. However, out of 88 cases collected from different sources all of 12 (nearly seven per cent.), which were primary, that is, which occurred without any other accompanying disease, appeared during the grip period, and as stated, 7 of these were observed last year. I also examined the records of the Presbyterian Hospital to learn if a corresponding increase had been noted there, but only 9 cases had been observed in the six years from 1888 to 1894, and these were quite uniformly distributed. The whole matter may be one of those curious coincidences with which medical experience abounds, but it is a strange fact certainly that of all the 88 cases cited, the average number occurring per year has been more than doubled since the grip first appeared among us. The prevalence of thrombo-phlebitis with grip has been commented upon by several recent writers, namely, Laache, Ducket, Orlandos, and Annequin.

An analysis of these cases reveals some interesting facts, which will be briefly discussed.

Termination.—By far the larger number of cases, seventy-four per cent., ended in complete recovery, three were transferred and lost sight of, and eight per cent. were improved. The average duration was between three and four weeks, but many of the cases, especially those involving the femoral or popliteal vein, were troubled for months with obstinate swelling of the leg whenever it was not kept in a strictly horizontal position. Eleven per cent. died, and from the stress which is usually laid upon the danger of embolism from detachments of portions of the original clot, it occasions some surprise that this could not be distinctly proven in any case and only seemed possible in one.

[1] A paper read before the Practitioners' Society, February 1, 1895.

The causes of death in the eleven cases were as follows: 1, carcinoma of gall-bladder; 2, 3, chronic diffuse nephritis; 4, tuberculosis, pleurisy with effusion; 5, lobar pneumonia (preceding the phlebitis); 6, pyæmia (preceding the phlebitis); 7, liver abscess (preceding the phlebitis); 8, thrombosis of portal vein; 10, cardiac thrombosis, possibly embolic, possibly independent of embolism; 11, not given.

The question of the frequency of embolism following the thrombosis is of very great practical importance in regard to the danger of bandaging these cases. It is generally regarded as unsafe to bandage at all while acute symptoms last and there is danger of dislodging portions of the clot. Many patients suffer intensely from pain in the swollen extremity, who could be relieved by bandaging if it were justifiable. One cannot help feeling, however, that this is a hazardous treatment so long as the condition of the clot remains uncertain.

When these patients convalesce and first begin to use the affected limb, it usually requires bandaging for some days or weeks to prevent swelling, and it is a difficult point to determine how soon this treatment is justifiable.

Etiology.—The main interest in the cases under discussion concerns their etiology. In general coagulation of blood within the body is attributed to one or more of three causes: 1. Alterations in the blood-vessels, including inflammation and injury of their walls. 2. Slowing of the rapidity of the blood-current, due to enfeebled heart action, or obstruction to the progress of the blood 3. Alterations in the blood itself.

1. Alterations in the blood-vessels as a primary cause of thrombo-phlebitis, *i.e.*, without extension of inflammation from cellular or other tissues, are believed to be rare. It is much more common for a thrombus to act as a foreign body and excite local inflammation in the walls of a surrounding vein, than for the vein to become primarily inflamed without extension of the process from contiguous organs.

Analysis of the diseases complicating the cases under consideration shows clearly that, with one or two exceptions only, there has been no such extension of inflammation. Thus the thrombo-phlebitis occurred in connection with typhoid fever, 23 times; pneumonia, 6 times; grip, 4 times. There were 3 cases each of pleurisy and chronic diffuse nephritis, 2 each of broncho-pneumonia, anæmia, and appendicitis (one septic), and 1 each of liver abscess, pyemia, septicæmia, carcinoma of the gall-bladder, endocarditis, meningitis, rheumatism, cardiac hypertrophy, gastritis, erysipelas, and ulcer of the leg. The last two might have involved extension of inflammation. On the other hand, a large number of these cases accompanied exhausting, infectious diseases, in which there is known to be change in the composition of the blood proteids. There still remain a dozen cases to be accounted for, in which there was no immediately associated disease of any kind discoverable.

2. It may be asked how far enfeebled heart action and alterations in the rate of blood-flow are responsible for the local coagulation. Certainly a feeble heart-action alone does not satisfactorily explain the clotting. There are too many diseases in which the heart force becomes much weaker than in many of the cases described without there being any such tendency, and

among these cases there were but two in which cardiac disease was prominent.

Undoubtedly, a slow blood-stream, or, rather, blood under slight pressure in the vessel, favors clotting in some instances, probably by allowing the leucocytes to accumulate within it; but there are many contradictory facts regarding this phenomenon. For example, bronchial hemorrhage is often controllable by ligating the extremities, so as to hold back the blood which they contain from the general circulation. When this is done, the bronchial vessels are under less pressure, and the blood stops oozing from them, but it neither oozes from, nor coagulates in, the veins of the extremities in which the current has been stopped entirely by the tourniquets.

It is possible to carefully ligate an artery or vein in an animal by two ligatures, placed two or three inches apart, and tied very gently, and yet the blood between remains fluid for several days, under no pressure and completely at rest. Yet a single ligature upon an artery causes coagulation. In a sacculated aneurism the blood may coagulate next the diseased walls, while it remains fluid in the actively moving stream; yet it does not always coagulate even when at rest, and when the vessel walls are much diseased, nor does it invariably clot in hæmatomata. Slow or feeble circulation alone does not, therefore, necessarily cause coagulation.

Some interest attaches to the site at which thrombophlebitis most often appears. In the 88 cases reported, 63, or about seventy-four per cent., occurred primarily in one or other femoral vein, 12 in the popliteal, 5 in the pulmonary veins, 3 in the cerebral sinuses, 1 each in the tibial vein, the portal vein, and the veins of the neck; 2 in the internal, and 1 in the external, iliac vein. A glance at a diagram of the relations of the femoral vein and its branches makes it easy to appreciate the peculiar arrangement of converging veins which focuses the blood-stream from so many different directions at one point in that vein. The quantity of blood received, the wideness of the vessels at this situation, with the possibility of occasional obstruction in passing beneath Poupart's ligament, produced by muscular contraction, and changes in the position of the limb, all favor stagnation of the blood-stream, in so far as that may be a factor in producing thrombosis. Yet there is no such arrangement in the tibial or popliteal veins, and here the blood-stream has but little interruption. In the cerebral sinuses coagulation might be expected to occur very easily, both on account of their arrangement and the fact that they are more or less subdivided by trabeculæ; yet coagulation is much less frequent here than in the femoral vein.

3. The composition of the blood may be altered. Blood which is abnormal in any respect may coagulate either more or less easily than usual, according to the nature of the change. We are familiar with the fact that in many diseases the post-mortem coagulation may be retarded, yet some of these are the very ones in which phlebitis is known to occur. For example, the blood coagulates poorly in pneumonia, pyæmia, rheumatism, and acute inflammatory conditions generally, and, according to Charcot, in grip.

If the blood coagulates in thrombo-phlebitis solely because of chemical changes in its composition, why should so many different diseases produce the same result; and, admitting the readiness of the blood to coagulate, why should it do so in so many different situations, and yet only in one small part of a vessel at a time, as is often the case? When an artery is ligated by the surgeon, the clot begins to form near the injured wall of the vessel at the ligature, and extends to the first large branch, *i.e.*, as far as the blood is at rest. But in a vein the clot does not always keep on extending to the nearest branch in either direction, nor does it always involve the whole of the column of blood which is at rest. Sometimes the phenomenon is met of a multiple phlebitis with clots in several different vessels, and one or two rare cases have been reported where such clots form, disappear, and reform elsewhere in the circulation.

If we believe that the main cause of clotting in thrombo-phlebitis is an altered composition of the blood plasma, it is difficult to explain why the coagulation does not involve more blood, especially in those cases in which there is no local obstruction and in which the heart action is still strong, as evidenced by its sounds, the force of the pulse, the capillary circulation, and the color and warmth of the skin. That this condition is not at all incompatible with the occurrence of thrombosis was demonstrated by several of the idiopathic cases above mentioned.

If it be conceded that a local inflammation of the vein precedes the clotting in many of these cases, the problem does not become much easier of solution, for, leaving out of count distinctly septic and embolic cases, what should excite inflammation primarily in so many different situations and yet so often in the same place, namely, the femoral vein? Moreover, phlebitis may continue and the vein finally reach a condition of advanced calcareous degeneration before a thrombus forms within it.

These are truly difficult phenomena to explain upon any one theory of coagulation. All that can be definitely said is that in the majority of cases of phlebitis some severe antecedent disease, commonly septic or infectious, produces alteration in the blood which causes it to coagulate in situations where some peculiarity in local condition obstructs or retards the blood-stream.

It will be appropriate in this connection to discuss the present theories in regard to intra-vascular coagulation, and the possibility of therapeutic modification of the coagulability of the blood. Originally the phenomena of coagulation were mainly studied in shed blood, but within a few years much valuable research has been expended upon the nature of the process within the vessels, and it has been discovered that intra-vascular clots may not only differ in the circumstances of their formation but in their actual composition, from the clots of shed blood. The theory of coagulation of shed blood, which has met with final acceptance by most physiologists, is that of Hammarsten, which is, briefly, that fluid intra-vascular blood contains a proteid, fibrinogen, in solution, which becomes solid fibrin through the influence of an unorganized ferment known as the fibrin ferment. The latter is now believed to be a compound of lime with proteid substance, a nucleo-lime-albumin. (Pekelhering.) This theory abandons the earlier ones that fibrin was a union of two separate substances, or that it was a part of a disintegrated complex substance. It is produced by a simple change in physical properties, somewhat as a hot gelatine solution "sets" when it cools, or as water turns into ice, only the agent is not a different degree of temperature but a ferment, and the actual process is different, being a variety of fermentation.

The origin of the fibrin ferment has occasioned as much controversy as the theory of coagulation itself. Dalton[1] wrote, "The evidence appears to be that it comes from the divided or injured vascular coats, or from the interstitial spaces beyond," but this theory was never really substantiated, and it wholly failed to account for the coagulation which may take place within uninjured vessel walls. Schmidt proved that the ferment exists in the white corpuscles, and since the description of the blood plaques or third corpuscles by Bizzozero in 1882, the function of ferment production has been assigned to them also. When blood is shed they quickly disintegrate, part with their fibrin ferment, which does not exist independently in the blood, and coagulation ensues.

Our knowledge of the rapid formation of the diges-

[1] Human Physiology, 1882, p. 229.

tive ferments at the moment of secretion, from previously existing substances called zymogens, makes it seem not impossible that the third corpuscles may produce the fibrin ferment from proteid materials present in the blood at the moment of their disintegration or death. This, however, is purely conjectural. A recent view of coagulation is advanced by Freund,[1] who leaves the ferment out of account, and holds that earthy phosphates from the corpuscles join fibrinogen to form fibrin in shed blood.

It is no doubt possible for clots to form within the blood-vessels in the manner just described of their formation without the vessels, but it is now well known that thrombi which have formed slowly, not at first completely occluding the lumen of the blood-vessel, are composed very largely of the corpuscular elements of the blood which have been held back, so to speak, from the passing current and which fuse together. Such thrombi may contain some fibrin, but intra-vascular clots have been described which consist wholly of white corpuscles and blood plaques. This is an interesting return to the old view of coagulation, for "nearly up to the end of the eighteenth century the clot was supposed to consist of merely adherent corpuscles." (Halliburton.) Late investigations have shown, however, that it is not the clot of shed blood but the thrombus which consists of corpuscles. Zahn declares that the breaking down of leucocytes always precedes thrombosis.

A new study of thrombosis was published last year by Wlassow in Jena.[2] He makes the problems under discussion still more complicated by introducing the red corpuscle as a more or less active agent, whereas heretofore it has been supposed that when found in a thrombus it was merely passively entangled there. He divides thrombi into three varieties, the white, the red, and the hyaline, and says that "The first condition of the white thrombus is the result of the sudden destruction and conglutination of red corpuscles." "The foundation of the white thrombus is not leucocytes, but other morphological elements." And he finds that the younger the thrombus the more red cells or chromocytes it contains, together with smaller granular masses staining with gentian violet, and which he believes are derived from the disintegrated red disks. There are also present mono- and poly-nuclear leucocytes, and the older the thrombus the more leucocytes it is seen to contain.

Halliburton finds that the blood which fails to coagulate in the mouths of the vessels in hæmophilia does clot when drawn, and the same is true in scurvy and hemorrhagic purpura. This emphasizes again the restraining influence of the living vascular walls upon coagulation, which was demonstrated by Brücke as early as 1857, and subsequently by Hunter and Lister.

The history of other coagulable substances than blood in passing through the body is interesting to follow. Take, for example, the course of the chief proteid of milk, casein. It is formed in some manner from the fluid blood by more or less solid cells in the mammary gland. We drink it in fluid form, and in the stomach, by the ferment rennin, it is immediately made solid or coagulated into curd, and thereupon at once redissolved by another ferment, pepsin, into a highly diffusible fluid proteid, or an albumose. It then passes through the more or less solid cells of the intestinal villi into the fluid blood, and, still fluid, it passes through the solid cells of the capillary walls into lymph spaces, and is possibly destined to enter into the composition of some solid structure and must finally become fluid again or go into solution to be split up, re-enter the blood-vessels, or enter the lymphatics, and be removed as waste through solid secreting cells in the tubules of the kidney, passing into fluid urine, and sometimes still further disintegrated and made solid again by crystallization in some form of nitrogen-containing substance.

[1] Med. Jahrb., 1888, p. 259.
[2] Beitr. z. Path. Anat. u. z. allg. Pathol., 1894, xv., 543–580.

We have here presented the phenomenon of an albuminous substance being put through half a dozen changes in density before wholly losing its identity as a proteid, part of which transformations are produced by ferments and part by the activity of living cells. It is not, therefore, a surprise that the living cells lining the blood-vessels may exert a controlling influence upon the density of the blood.

The theory has been somewhat lately advocated by Mills, of Montreal, and others, that the cells lining the capillaries are true gland cells, and there is much to strengthen this belief in the selective action which they seem to exercise in taking out certain substances from the blood and withholding others.

In the liver materials pass through the capillaries which do not do so elsewhere, and the various fluids which abnormally collect in serous cavities after oozing through capillaries and serous membranes differ in composition. The remarkable tendency that the blood displays to recover and maintain a uniform normal density, reaction, and composition, after severe hemorrhage, for example, is far more likely to be due to a vital action of the capillary cells and other gland structures than to any inherent property in the blood itself.

If it be admitted that these capillary cells regulate the density of substances which pass through them and of the fluids with which they are in contact, namely, blood on the one side, and often lymph on the other, may they not also conceivably sometimes affect intravascular coagulation by their control over the composition of the blood?

Ehrlich has stated his belief that "the coarsely granular leucocyte is a unicellular gland," and Kantback and Hardy[1] have shown that the degree of granulation is affected by bacterial irritation in a manner which suggests the alteration in appearance of cells like those of the salivary glands under stimulation.

In commenting upon these results, Sherrington, by a series of most instructive observations upon changes in the blood in inflammation, leaves the question of the degree of this gland-like action of leucocytes somewhat in doubt, but in all the discussions of the causes of intravascular coagulation, the leucocyte still holds prominence as one source, at least, of the fibrin ferment.

The coagulation phenomena produced in albumin by heat or acids, or in muscle fibres in passing into rigor mortis, are not identical with the coagulation of blood fibrin by ferment; yet, as has been shown above, there are some thrombi which are apparently wholly composed of agglutinated corpuscles, which in some cases may perhaps adhere in masses without the agency of a ferment and without the formation of fibrin.

Therapeutics.—The possibility of modifying the coagulability of the blood within the body by practical therapeutic means has only quite lately been demonstrated, and it has been proved that this can be done both as regards the firmness of the clot and the promptness of its "setting" when drawn, and that these conditions can either be intensified and accelerated, or diminished and retarded, respectively.

For example, A. E. Wright[2] reports some very striking results from internal administration of calcium chloride in two-gramme doses. This treatment is based upon the well-known fact that the addition of minute quantities of neutral salts to blood hastens its clotting, and according to Green,[3] and Ringer[4] "lime salts are essential for the efficient formation of fibrin and for the activity of the fibrin ferment." This applies especially to calcium sulphate, and upholds the nucleo-lime theory of coagulation previously mentioned.

Wright's most interesting cases were in four families the members of which had hæmophilia. In every instance he was able to accelerate the coagulation of

[1] Proceedings of the Royal Society, December, 1892.

[3] Journal of Physiology, viii.
[4] Proceedings of the Physiological Society, February, 1890

their blood, and in one case the use of the lime salt enabled an operation for removal of nasal polypi to be conducted with safety. He has also succeeded in controlling epistaxis and pulmonary hemorrhage by this simple and apparently efficient means. In some instances he reduced the coagulation time of such blood from nearly an hour to one or two minutes.

Another method which he employed for the same purpose was that of cautious inhalation of carbonic-acid gas, but this treatment is certainly hazardous, especially for a person already reduced in strength by hemorrhage, and it is difficult to understand, for venous blood always coagulates slower than arterial, and a stream of carbon dioxide gas sent through shed blood saturates it and precipitates the fibrinogen in minute flocculi, of course preventing the formation of fibrin by destroying its source. However, Wright reports the successful treatment by CO_2 inhalation of a boy having hæmophilia and who was bleeding to death, and he also used it with benefit, as he thought, in the case of a large aneurism. Strangely enough carbon dioxide gas, which ordinarily prevents coagulation of shed blood, under certain conditions prevents the inhibitory action of albumoses upon that process.

Wright further experimented upon the means of retarding coagulability of the blood, and this question is of more immediate interest in connection with the possibility of preventing the extension of a thrombus once formed.

There are many substances which prevent coagulation when added to shed blood which cannot be made to act when absorbed through the stomach, probably because they are decomposed by the digestive fluids. Such are leech extract and solutions of peptones or rather of hetero-albumose (Pollitzer).[1] The latter, however, acts temporarily in the dog when transfused directly into a vein. Some materials influence coagulation in the blood of one animal and yet fail in that of another. Thus the albumoses which inhibit clotting in dog's blood have no effect upon that of the vegetarian rabbit.

Oxalates, tartrates, and citrates all retard coagulation of shed blood. The first-named salts are too poisonous for internal use by man, and the others, according to Wright, fail to act when given per os.

He discovered that the acids of these salts, tartaric and citric, have a decided inhibitory or retarding action upon intra-vascular coagulation when administered internally, and he maintains, contrary to general experience, that in cases of scurvy with persistent hemorrhage from the gums, the use of fresh lemon-juice may tend to keep up the oozing of the blood. He says that the neutral citrates and tartrates should be given in such cases, but not fresh lemon-juice.

It has long been known that the neutral salts of the alkaline earths, alkaline chlorides, sulphates, phosphates, nitrates, and carbonates are capable of inhibiting coagulation, but they have to be added in concentrated or saturated solution, and in considerable bulk, usually half-and-half, and if subsequently diluted, coagulation is still possible.

In experimenting upon the blood-pressure of dogs, whose blood coagulates even more promptly than man's, I have often endeavored to prevent coagulation in the cannulæ employed, by previous intra-venous transfusion with salt solution, but not until many ounces of such solution have been added to the blood, amounting to nearly half its volume, is coagulation materially affected. There are some fourteen pounds of blood in the human body, and it would not be possible to make therapeutic use of these salts to prevent the formation of coagulæ, and small doses, as in the case of calcium chloride, may only favor the process.

I have been interested recently in experimenting upon the influence of the extract of the thyroid gland upon the blood, and have found that it has a very decided effect upon coagulation, both in accelerating the process and in increasing the firmness of the clot. It has been shown that extirpation of this gland is accompanied by a reduction in the number of red and an increase in the number of white corpuscles,[1] and further that it reduces the oxyhæmoglobin of the arteries and increases the venosity of the blood. The latter condition at least might be expected to retard coagulation in the absence of the gland. On the other hand, I found that when the desiccated substance of sheep's thyroid was added to shed blood, coagulation occurred much quicker, and the resulting clot was much firmer than normal.

It is difficult to determine with absolute accuracy the density of a series of blood-clots. The method employed was to note, 1. The first moment of apparent viscidity of the blood. 2. The earliest moment at which the containing receptacle could be inverted without the clot falling out. 3. The quantity of serum expressed by the clot upon standing for a fixed number of hours.

Glass receptacles of equal size were used, which were filled with equal volumes of blood drawn from a cannula inserted in the femoral artery of anæsthetized dogs. In all cases control experiments were made, because the rapidity of coagulation and firmness of the clot normally varies slightly in different animals.

A summary of these experiments, which were repeated many times with the same result, is as follows: Normal dog's blood alone, 10 grammes withdrawn, became viscid in one minute; gelatinous in four and one-half minutes; firmly adherent to vessel in thirteen minutes. Ten grammes dog's blood with 3.5 c.c of aqueous extract of powdered thyroid became viscid in one minute; gelatinous in two minutes (less than half the normal time); adherent in seven minutes.

The same result occurred with alcoholic instead of aqueous extract. Some precipitation of albumin resulted, interfering with the shape of the clot, but the blood became gelatinous in one and one half minutes. Ethereal extract caused a similar result.

With a glycerine instead of the aqueous extract the blood became viscid in one-half minute; gelatinous in two and one-half minutes; firmly adherent in four minutes.

I next sought to determine the effect of the thyroid extracts upon coagulation when injected into the blood-vessels. The various extracts above mentioned were injected through a cannula directly into the jugular vein in different animals and allowed to remain long enough to thoroughly commingle with the circulating blood. In each case thirty grammes of diluted extract, representing ten grains of powdered thyroid, were used. A specimen of normal blood became viscid in one minute; gelatinous in four minutes; firmly adherent in twelve minutes. With both alcoholic and glycerine thyroid extracts the blood became viscid in one-half minute; gelatinous in one minute; firmly adherent in three minutes, or one-fourth the usual time. The animals were kept alive under ether for some time, when as no apparent change occurred in the circulation, respiration, or temperature, they were killed. The blood throughout was fluid.

In another series of experiments it was found that successive samples of blood withdrawn from the same animal at intervals of five minutes, after glycerine extract had been injected, exhibited progressive firmness of coagulation, indicating that the influence of the thyroid was becoming more diffused throughout the vascular system. This blood, drawn into a saturated solution of sodium sulphate, failed to coagulate, showing that the action of the thyroid powder was not sufficiently strong to overcome the usual inhibitory influence of that salt. On removing the clots from the glass vessels the one with glycerine extract of thyroid was by far the firmest and smoothest. It was unusually hard, much more so than the normal clot ever becomes.

[1] Journal of Physiology, vii., 282.

[1] Horsley: British Medical Journal, January 30, 1892.

Control experiments were made by adding to the blood similar quantities of water, alcohol, ether, and glycerine each alone. In every case the coagulation was distinctly less firm than when the thyroid extract was used.

Landois[1] and Kirkes[2] mention glycerine among those chemical agents "which hinder or delay coagulation." To do this it must be used in considerable quantities, as pointed out by Charles.[3] In these experiments I found that injected into the circulation in very small amounts, it distinctly accelerated coagulation and produced a very firm clot, although the blood became "lake." The glycerine extract of thyroid powder, however, produced a much firmer clot than the glycerine alone, a result which was confirmed by repeated tests, and the observation of several persons who examined the clots without previous knowledge of their composition.

Several of the samples first drawn were kept for twenty-four hours, when it was found that the clot had shrunk so firmly as to express an equal volume of serum, more than three times as much as that expressed by the normal clot.

Control experiments were made by injecting identical quantities of alcohol and of ether with those used in the other animals, but without the thyroid extract. They showed very slight increase in the rate of clotting and the firmness of the clot, but nothing commensurate with the influence of the thyroid extract.

The conclusion is, that the thyroid gland contains some substance, possibly a ferment, which is capable of extraction by glycerine or otherwise which hastens coagulation of shed blood both when previously injected in the body, and when added after its withdrawal, and which increases the firmness of the clot as well.

Godart and Slosse[4] found that after injection of thyroid extract into the right external jugular vein of a dog, the volume of lymph was increased and it became non-coagulable, less aqueous, and more viscous. It appears, therefore, that the thyroid extract acts differently upon the coagulability of the blood and lymph. Woodbridge procured from a watery extract of the testis and thymus gland a substance which causes immediate death by general coagulation when injected into the veins.

These experiments demonstrate the curious fact that blood can be so altered in composition as to coagulate in one-third or even one-fourth of the usual time and form a much firmer clot which expresses triple the normal quantity of serum, and yet not coagulate while still circulating within healthy blood-vessels. I have lately seen an unusual case of this type in a lady who was referred to me for blood examination by Dr. Loveland. She is about sixty-four years of age, active, and in good general condition, but for two years she has suffered from a vasomotor neurosis causing annoying suffusion of the capillaries of the face and neck. This led to an examination of her blood, and the red corpuscles, to my surprise, were found to number approximately seven and a half millions, and the hæmoglobin, as measured by the Fleischl hæmoglobinometer, was one hundred and thirty per cent. On withdrawing blood from the punctured finger it congealed almost immediately, in one-sixth the usual time, and formed so firm a coagulation in two minutes that it took considerable rubbing to detach it from the finger. The patient's heart and circulation appeared normal. Here was an instance of greatly concentrated blood, coagulating when shed with several times the normal energy, and yet with no evidence or history of any intra-vascular coagulation.

Dr. Loveland has lately reported other examinations of the blood[5] in a series of cases, in one of which the red corpuscles numbered 10,600,000, in another 8,940,000, in one 8,620,000, and in six others over 7,000,000 per cubic millimetre. The hæmoglobin was correspondingly increased, in two cases to one hundred and forty-five per cent. Yet in none of these cases, as he informed me, had there been any special tendency to intra-venous coagulation, although the density of the blood was so greatly increased.

It has just been shown that blood of double the normal number of red corpuscles is not too dense to circulate freely, and that blood which coagulates in less than half the usual time when shed, does not necessarily do so within the body. It is equally true that anæmic and watery blood, and even leucocythæmic blood containing an enormously increased proportion of the ferment-holding leucocytes, does not necessarily coagulate any more easily. Anæmia accompanying debility from exhausting diseases may be complicated by thrombo-phlebitis, but severe primary anæmia and chlorosis have not been observed to furnish any marked predisposition to it, although it may occur in these diseases. Cockle has reported five cases of thrombo-phlebitis with chlorosis, two of which were in the cerebral sinuses and the other three in the legs, and Laache reported similar cases.

"In pernicious anæmia the blood, when shed, coagulates with difficulty" (Eichhorst).

Outside of the body, dilution of the blood with water added in any proportion short of fifty per cent., either alone or with a neutral salt, favors coagulation, although the resulting clot may be less firm; but water injected within the blood-vessels, or transfused salt solution, has not been found especially liable to occasion thrombosis. Uric acid and lecithin both favor coagulation in shed blood, yet gout is not often accompanied by thrombosis. It is mentioned but once in the series of cases herein reported.

Halliburton states his belief that pathological intra-vascular coagulation of the blood "may be from an alteration in its chemical constitution, as after certain acute specific diseases, such as typhoid fever, or after pregnancy (phlegmasia dolens), the nature of which chemical changes is not known." And he goes on to say that "In other cases the intra-vascular coagulation is due to the absorption or experimental injection of poisonous substances into the circulation. These are probably proteid in nature. Thus in a wound in which the discharge is pent up the absorption of such exudation will in mild cases bring on a rise of temperature causing one form of surgical fever, but in other cases will cause intra-vascular coagulation. The material which produces these poisonous effects is probably the fibrin ferment; the normal body has the power of resisting this substance to a very great extent."

In consideration of all the facts above reviewed it seems to me, on the whole, most probable that thrombo-phlebitis is ordinarily produced, not by modifications in the number or quality of the leucocytes or chromocytes, nor yet in the fibrin antecedents, not solely by modifications in the blood-stream or vascular walls, but by the addition to the blood of some proteid product which is either identical with the fibrin ferment, or which has a similar coagulating power.

Finally, it is possible, although it cannot yet be definitely asserted, that this proteid is developed from albumoses formed in the blood or absorbed from the tissues and produced as a result of the action of micro-organisms.

In conclusion, I may say that I feel that I have dealt with an unsatisfactory subject in that many questions have been raised which are difficult if not impossible to answer in the light of our present knowledge of coagulation. To me this subject has always been one of the most interesting and extraordinary of what for lack of better term are sometimes called the "vital phenomena." The blood has tempted many experimenters to solve its mysteries, and in many respects the further one studies coagulation the more inexplicable it be-

comes. However, that we may perhaps derive some practical knowledge from those present, I would suggest for discussion the points which have been raised in regard to, 1. The frequency of thrombo-phlebitis. 2. Its etiology, especially in relation to grip. 3. The possibility of modifying the coagulability of the blood by therapeutic measures, in any disease.

THE PRESENT STATE OF OUR KNOWLEDGE OF GOUT.[1]

By LOUIS FAUGÈRES BISHOP, M.A., M.D.,

NEW YORK.

Introduction.—Gout is a subject which has not been publicly discussed in this Section for a long time, and I therefore venture to present an outline of the subject together with a review of certain definite additions to our knowledge that have been made during the last few years.

Historically there is no disease more interesting than gout, whose name is associated with great physicians and illustrious patients in all ages. Hippocrates, Celsus, and Galen had a fairly correct idea of this disorder. To those great founders of chemical science, Wollaston and Scheele, we owe a debt for light thrown upon the chemistry of this disease. It is in England that we find the greatest number of eminent names associated with the literature of gout; but that of the earliest, the great Sydenham, still shines the brightest of them all. To England, also, we are indebted for the latest important advances, through the work of Sir William Roberts and a much younger man, Alexander Haig.

The name gout, once applied in a more restricted sense, is now made to include all the conditions due to the gouty diathesis. It has this advantage over the newer terms, lithiasis or lithæmia, that it does not imply any definite theory of the disease.

Theory.—The theories of gout have been many. With them are associated among many others the names of Cullen, Garrod, Roberts, Duckworth, and Haig. Of these, some are still living and working at the problem.

From the earliest times theories of gout have prevailed, predicating a foreign substance circulating in the blood. Deposits of foreign material in the tissues have always been noticed. Before the time of the development of chemistry there was much speculation and ingenious guessing as to the nature of this blood poison and of the gouty deposits. An old writer, named Hoffman, defended with some degree of poetic justice the belief that the accumulation in the joint was the same as the tartar that accumulates in wine-casks. Wollaston by chemical analysis determined once for all that the gouty deposits were urate of soda. Urate of soda in the blood was discovered by another chemist, Scheele, who, though a poor apothecary all his life, yet was one of the best chemists of Europe. Chemical science, when it acquires territory by discovery, does not recede, therefore we can regard these things as fixed. Later writers have been devoted to the discovery of the sources, proportions, and relations of the urates rather than to the discovery of any other new element. In knowing that the urates in their various relations are a manifestation of a gouty condition we have not gone far enough. For that reason a number of theories have been propagated. Cullen advanced nervous theory, appreciating that the gouty diathesis was an expression of a general disturbance of the body. He blamed the nervous system as the controlling influence. Sir Alfred Garrod, though historically not the author of the uric-acid theory, is still well entitled to its credit because of his many careful studies, which have convinced men of its truth. He showed that there was an increase in the uric acid (of course in combination) in the blood, due either to increased production or to diminished elimination, and believed that the alkalinity of the blood was also lessened. He supposes that the urate of soda is deposited because when the alkalinity of the blood is diminished it no longer holds it in solution. The urates being deposited about a joint, inflammation naturally follows.

Sir Dyce Duckworth advocates a theory which may be called the neuro-humoral theory. He believes that not merely one organ or two organs are at fault, whereby uric acid is formed at times in excess, but that there is a neurosis of the nerve-centres, and a peculiar incapacity for normal elaboration within the whole body.

Ebstein's theory is interesting. He believes in a nutritive tissue disturbance, leading to small necrotic areas in which the urates are afterward deposited.

Sir William Roberts's study of the chemistry of uric-acid compounds, as detailed in his Croonian Lectures in 1892, mark a distinct advance in our knowledge, and will repay a detailed study. His work was conducted in the careful, scientific manner characteristic of a good chemist, but controlled by the broader views of a clinical observer. These lectures are a good example of the kind of work by which real advances in medicine are to be accomplished. We cannot follow in this place his chemical reasoning and experiments. His first important result was a determination of the chemical composition of the amorphous urates. It surprises one to think that only so recently have we obtained a definite knowledge of the structure of this very familiar urinary deposit. Roberts proves that the amorphous urates are quadriurates. Representing the uric-acid radical by $\overline{U}$, we can represent the formula by $H_2\overline{U}$, $MH\overline{U}$. In this formula M represents the base. I quote:

"The chemical reactions which are concerned in the spontaneous precipitation of uric acid in acid urines are very interesting to trace out. It is certain that uric acid always subsists in the unchanged urine as a quadriurate. The urine in which this substance is dissolved is a watery solution which contains a number of mineral salts. Among the salts the most important, in regard to the point under consideration, are the alkaline phosphates. These regulate, in the main at least, the reaction of the urine. The phosphates easily oscillate between the monometallic forms, or superphosphates, which have an acid reaction, and the dimetallic forms, which have an alkaline reaction. When the former preponderate, as is usually the case, the urine is acid; when the latter preponderate, the urine is alkaline.

"We have, therefore, in an acid urine the quadriurate existing in the presence of water and of superphosphates. These conditions insure the ultimate complete liberation of the uric acid. The first step in the process is the splitting up of the quadriurate by the reaction of the water of the urine into free uric acid and biurate. By this reaction half the uric acid is set free. But the biurate resulting from this reaction is immediately retransformed in the presence of superphosphate by a double decomposition into quadriurate. Two atoms of biurate with one atom of monometallic phosphate change into one atom of quadriurate and one atom of dimetallic phosphate, according to the subjoined equation:

$$\underset{\text{Biurate.}}{2\,(M\,HU)} + \underset{\substack{\text{Monometallic}\\\text{phosphate.}}}{(MH_2PO_4)} = \underset{\text{Quadriurate}}{(H_2U,\,MHU)} + \underset{\substack{\text{Dimetallic}\\\text{phosphate.}}}{(M_2H\,PO_4)}$$

"These alternating reactions—breaking up of quadriurate by water into biurate and free uric acid and recomposition of quadriurate by double decomposition of biurate with monometallic phosphate—go on progressively until all the uric acid is set free."

Having worked out the chemistry of the quadriurates Roberts proceeds to consider the effects of various conditions upon the precipitation of uric acid, but this has a more important bearing upon the subject of gravel

[1] A paper read before the Section on General Medicine of the New York Academy of Medicine, March 19, 1895.

than of gout. He draws the following important conclusions concerning uric-acid precipitation in gout: He believes that the normal physiological condition of uric acid in the body is that of a quadriurate, and that any departure from this condition must be regarded as pathological. He traces the changes which the quadriurate undergoes in the blood leading to the production of sodium biurate and its deposition in the tissues. *He finds that the solubility of sodium biurate is as follows: In pure water at 100° F., about one part in a thousand; in water containing one-tenth of one per cent. of sodium bicarbonate, the solubility was diminished one-half and progressively diminished as more bicarbonate was added.* The same principle was brought out by experiments with sodium chloride, sodium sulphate, sodium salicylate, and sodium phosphate. On the other hand, the effects of different quantities of potassium carbonate, potassium chloride, and potassium phosphate upon the solubility of biurate of soda were very slight. Calcium salts diminished solubility like the sodium salts.

Sir William Roberts sums up as follows: "The influence of a salt depends exclusively on the nature of the base, and has no reference to the acidulous radical with which the base is combined. *Salts with an alkaline reaction, such as carbonates and phosphates, do not differ in the least from neutral reacting salts, such as chlorides and sulphates.* Salts of soda exercise a strong deterrent influence, and the deterrent influence increases with the increasing percentage of the salts in solution. Salts of lime, magnesia, and ammonia have also a deterrent effect, but slighter than that of salts of soda. Salts of potash have no effect either way."

The existence of a gelatinous or hydrated modification of the urates would seem of much interest, because it is easy to imagine such a gelatinous form being deposited in the tissues, and afterward reverting gradually to the crystalline form.

Roberts's summary of the history of uric acid cannot be better given than in his own words: "The facts elicited enable us to obtain a coherent view of the state and destiny of uric acid in the body. It has been shown that in normal urine uric acid always exists as a quadriurate, and that in animals which eliminate their nitrogen as uric acid, like birds and serpents, the urinary secretion is composed entirely of the same combination. Proof has also been furnished that in liquids containing alkaline carbonates, such as the serum of the blood and its derivatives, lymph and synovia, uric acid passes into solution in the first instance as a quadriurate. From these considerations it may be inferred that in the normal state uric acid is primarily taken up in the system as a quadriurate, that it circulates in the blood as a quadriurate, and that it is finally voided with the urine as a quadriurate. In perfect health the elimination of the quadriurate proceeds with sufficient speed and completeness to prevent any undue detention or any accumulation of it in the blood; but in the gouty state this tranquil process is interrupted, either from deficient action of the kidneys, or from excessive introduction of urates into the circulation, or from some other cause, and the quadriurate lingers unduly in the blood and accumulates therein. The detained quadriurate, circulating in a medium which is rich in sodium carbonate, gradually takes up an additional atom of base, and is thereby transformed into biurate. This transformation alters the physiological problem. The uric acid, or rather a portion of it, circulates no longer as the more soluble and presumably easily secreted quadriurate, but as biurate, which is less soluble, and probably also—either for that reason, or because it is a compound foreign to the normal economy—less easy of removal by the kidneys. The biurate thus produced exists at first in the gelatinous modification, but with the lapse of time and increasing accumulation it passes on into the almost insoluble crystalline condition, and then precipitation becomes imminent, or actually takes place."

Passing from this very inadequate consideration of Sir William Roberts's work, let us consider that of Alexander Haig. It is an interesting contrast to that of the former in that it is founded to a large extent on clinical observation with himself as a patient. In the investigation of recurrent migraine he arrived at certain conclusions after elaborate clinical and chemical investigation. After trying a great variety of alternations of diet, he gave up all butcher's meat and replaced it by milk and fish. On this diet the headaches disappeared by the intervals becoming longer, until finally he went eighteen months without an attack of notable severity. In searching for the cause of this phenomenon he discovered the relation between his headache and the excretion of uric acid, and he discovered means by which he could control the excretion of uric acid from day to day, or from hour to hour, and that in altering the uric acid he could alter the symptoms relating to it. He noticed that when he produced an increased excretion with alkali, he produced the headache, mental depression, etc., and when he stopped the plus excretion with an acid he removed all these symptoms. But he noticed that in curing the headache by giving the acid he produced a certain amount of shooting pain in the joints, the meaning of which probably was that the uric acid which failed to appear in the urine must have been held back in the joints and produced pains. The headache depended upon the absolute quantity of uric acid circulating in the blood.

Haig's interpretation of the phenomenon is as follows: He supposes that gouty symptoms are due to an accumulation in the body of uric acid depending upon a diminished excretion. He points out that if excretion falls behind secretion by a minute quantity in the course of time there will be an accumulation. He supposes that so long as this accumulation is quietly stored up in the tissues there are no constitutional symptoms, but when for any reason this is liberated and circulates in the blood the symptoms appear, and naturally enough an excess appears in the urine. This theory certainly explains very well the increased excretion that he observed at the time when symptoms were present or imminent. This also explains the periodicity of attacks. He believes that in persons in whom the balance of secretion and excretion is but very slightly deranged there is a very gradual accumulation, and that such persons will suffer from gout in some of its more obscure forms after years have elapsed.

Though Roberts and Haig have thrown light upon the chemistry of gout, it is evident that there is something more underlying the condition. Many good observers and thinkers, when viewing gout in connection with heredity and its many various manifestations, have felt convinced that the nervous system was a strong factor in its production. In explanation of the symptoms of acute gout the inflammatory reaction due to the deposits in the tissues of the biurate is sufficient, but in the explanation of the symptoms of chronic gout, affecting as it does the organs in various parts of the body, the mechanical theory has heretofore not seemed sufficient. The uric acid has been spoken of as a poison circulation in the blood. For a belief in the poisonous action of uric acid in any quantity that could possibly be present in the blood there is no foundation in experiment or observation. A more accurate explanation is probably the occurrence of precipitations of crystals of biurate of soda in various tissues of the body. It can easily be believed that so soon as the supersaturation of the blood is no longer present these are again taken into solution, though the damage may remain. Certainly the pricking pains so familiar to gouty people could be explained in this manner.

Symptoms.—*Acute Gout.*—The descriptions of all who have observed a first attack of acute gout in a young person show a surprising uniformity in the symptoms presented. The attacks come in the early

morning hours without previous warning. The patient is aroused by a severe pain in the metatarso-phalangeal articulation of the great toe. The pain has been a subject for description by writers of all times. Hippocrates as a medical man and Lucian of Athens as a poet described it long ago. Our own Benjamin Franklin turned aside from political duties to write a most vivid description of this pain. All seem to agree that the pain is a very bad one. Following the onset of the agonizing pain the joint swells, becomes hot, tense, and shiny. There is much fever and restlessness. Toward morning the severity of the symptoms subside, to reoccur again the next night, and so on for four or five days. All authors seem to agree that a very characteristic point is that the inflammation is followed by desquamation. To us in America this is not a familiar picture. We omit for want of time a consideration of the symptoms of chronic gout.

Irregular Gout.—In the absence of a sufficient experience with acute gout, we are apt, even when we recognize irregular manifestations, not to feel sufficiently that their successful management will depend upon keeping clearly in mind their relationship with the acute condition. We have all been taught to look upon gout as a cause of eczema; our attention has sometimes been directed to it as a possible cause of gastro-intestinal disorders. The teachings in this country in respect to cardio-vascular symptoms direct the student's attention too exclusively to the kidneys. We have attributed many nervous manifestations caused by uric acid retained in the system to other causes.

It is more in the appreciation of these irregular manifestations of lithæmia that there has been an advance from the older writers. Since Sydenham's time no one has improved upon the clinical description of regular gout. This is not surprising when we consider the wonderful good judgment of this man, combined as it was with great powers of observation, and above all with the fact that for thirty-five years before writing his article he had suffered severely from gout himself, and had carried out extensive observation and experiment upon his own person. Sydenham is called the English Hippocrates. His writings are delightful reading at the present time.

Distribution.—This brings us to a consideration of the occurrence of the gouty diathesis in various parts of the world, especially our own country. Since Sydenham's time, England has remained famous for gout. Sir William Savory says that in some one or more of its various phases a large proportion of the population of England do not attain advanced age without some personal experience of it. In Germany it occurs, but the name gout is there given to a large number of cases which English-speaking people call rheumatic. In America we have been fairly free from gout as compared with our English cousins, but still it may be possible that gout is more frequent than we like to believe, expressing itself in atypical ways. We have escaped because gout is a disease of old nations. A mixing of races always weakens hereditary diseases. Another reason that may be thought of is the comparatively small amount of sour wine consumed in this country. Unfortunately we are rapidly outgrowing these conditions; our population becoming more fixed, the growth of native wine with the springing up of a leisure class are factors which may well lead us to expect more typical cases of gout than in the past. May it not be, however, that we have been deceived in thinking gout less frequent in this country because we have overlooked irregular expressions of it? Granting the nervous system as a cause and disturbance of digestion as an occasion of gout, may it not be that the predominance of the nervous cause, in the absence of excess in eating and drinking, has led to the gradual establishment of gouty conditions without the intervention of acute attacks? Americans are temperate people in regard to drink, but an intemperate people in the expenditure of nervous energy, and if the nervous system, which presides over the chemistry of the body, is maltreated and suffers, in turn it will not be surprising if the chemical manipulations result in uric-acid compounds instead of urea.

Another thing that covers up cases of gout is a primitive habit that we have of naming symptoms instead of pathological conditions. When a layman or nurse speaks of dropsy as a disease, we say indignantly that it is only an expression of disease, but how often we write in our case-book "neuralgia," "headache," "neurasthenia," and like terms, when we know if we stop to think that we are falling into the same habit as the person who calls dropsy a disease, and it is more than likely that often we are mislabelling gouty conditions.

Our eminent countryman, Fordyce Barker, is quoted by Fothergill as saying of us, his countrymen, in connection with gout, that we "do not know it when we see it." Fothergill goes on to remark "that gout cannot be demonstrated in a test-tube, or mounted on a slide with Canada Balsam, though Garrod's 'thread test' can often be utilized no doubt."

The same authority, in the introduction of his popular book, "Gout in its Protean Forms," says "the anomalous and especially the nervous manifestations of gout have been considered at some length, there being a general consensus of opinion that these forms of gout are on the increase at the present time as compared with regular articular gout." Gout has always been a disease better recognized by older than younger practitioners, and the reason seems to be that the symptoms which are the outcome of a condition of the blood laden with uric-acid compounds are very numerous and various. The instruction in colleges and in hospitals teaches a man to recognize and expect to find well-marked cases of disease; the instruction of private practice alone teaches one to appreciate the existence of obscure conditions giving rise to many slight symptoms, extending over a part or a whole of the patient's life.

In reviewing literature of gout it has become plain that a considerable number of symptoms which in daily practice have been attributed to neurasthenia are definitely considered as gouty in their origin by men who have the confidence of the world. This is especially true of the muscular pains, the tender joints, the disturbances of sensation of middle-aged people. It has long been difficult to understand the distribution of these symptoms in connection with neuritis or functional nervous diseases. Neurasthenia is a sufficiently definite condition for us still to diagnose it with confidence in many cases, but with the proper conception of the scope of gouty symptoms, we can write gout many times where we have been accustomed to write "neurasthenia?"

The fact that urate of soda can be deposited quite suddenly when supersaturation of the blood exists and quickly redissolved when the blood is less than saturated explains very well the possibility of transient gouty symptoms. The crystals form in the tissues, do their damage, and disappear. This applies especially to the more internal structures of the body, for when deposited near the surface or in the cooler and more sluggish extremities the deposits have a greater tendency to remain.

Treatment.—There is a habit among all those who discuss the treatment of gout which has led to much misapprehension and much misplaced attention. It is the habit of speaking of uric acid with an emphasis on acid. Of course we all know that we usually mean uric acid in combination. The reaction of the blood is never acid. Roberts has shown that the solubility of urates is not influenced by the degree of alkalinity as far as laboratory experiments could prove this point. It would seem that we must forego the habit of speaking of the gouty diathesis as an acid condition of the

system. That the use of certain alkalies has been useful therapeutically has not been on account of their reaction but the particular bases present in them.

In expressing these views we have regard to the arguments and experiments of Roberts, though, of course, they are directly opposed to those of many other writers.

Haig found that phosphate of soda increased remarkably the excretion, but also increased the amount in the blood, the excess, he thinks, coming into solution from the liver, spleen, and tissues. He found that acids, lead, and iron interfere with its solubility, and therefore with its elimination. His views concerning lithia are worthy of attention. He remarks that although lithia is a beautiful solvent of uric acid in the laboratory, the laboratory also shows us that it forms an insoluble compound with phosphate of soda. Now phosphate of soda is so abundant in the blood that it is incomprehensible that lithia taken by the mouth can get at the urates without coming in contact with the phosphate of soda. This is directly opposite to the testimony of good clinical observers, and certainly of the immense volume of literature upon the subject of lithia waters that comes to us in our daily mails, but it is not an unreasonable suspicion that the chief value of these waters lies in the increased quantity of water taken by those devoted to their use.

It might not be out of place here to allude to the bottled-water craze. I say bottled water because an examination of the formulæ given by the people who advocate their use often shows that the only difference between the waters they sell and the water that may be had from the Croton faucet, or from any farm spring, is that one comes from bottles and the others from pipes.

In the absence of an acquaintance with quantitative chemical analysis the attention of the average man is so much concentrated upon the imposing list of ingredients written out for him in full of chemical terms, and printed in heavy type, that his attention is diverted from the local decimal figure which represents an amount per dose of the water so small that one must be mathematician to appreciate such a quantity. It is a fundamental property of decimals that the more zeros between the decimal point and the first figure representing value, the smaller the quantity they stand for, and yet the impertinent agent of a mineral water will occasionally point with pride at the size of these decimals.

It is time that medical men should cease allowing themselves to be imposed upon by such childish frauds, and keep at hand an analysis of Croton water, so that when prescribing the identical water to a patient they may patronize the pipe instead of the bottle, and save the patient from enriching some adventurers.

The treatment of an acute attack of gout is conducted on much the same principles as that of a like inflammatory condition in any other disease, but the constitutional cause must always be borne in mind. As to the advisability of giving drugs antagonistic to the disease at this time there has been much discussion for a great many years. Authorities have swung back to the original idea that drugs may be used. Much more important on account of the larger number of cases is the treatment of chronic gout. This must be to a great extent hygienic. Diet should be plain, moderate in quantity. Fluids, as milk, mineral waters, and plain water itself, should be taken abundantly. A regular life with plenty of fresh air and freedom from mental overwork or worry are of extreme importance. It is not as easy to be so sure as to exactly what foods are best as it is that the quantity must be moderate. Most people after middle life take much more food than is necessary. Starchy and saccharine foods must be limited, not so much because they themselves are dangerous as that they tend to disorder and weaken the digestive system. Fresh vegetables, which we are so fond of recommending, but which so often are hard for people to get, may be taken freely. A gouty person should avoid unreasonable dishes; alcohol in all forms should be avoided. When it is necessary or unavoidable the acid wines, such as champagne, must be avoided, and alcohol given in the form of good whiskey. All intoxicating liquors may be regarded as a mixture of alcohol, water, and other constituents which may be grouped together as giving the taste to the liquor. This latter group may or may not be injurious, but when we are seeking an alcoholic effect it is just as well to choose a mixture in which this latter group is present in the smallest quantity. Good whiskey supplies us with such a mixture. A strong person is often benefited by cold bathing, but this is not to be recommended except to such as are vigorous, and is not to be continued if found to be injurious. The fact that mineral waters are so much more successful when taken at the springs is due to the regimen, which can be enforced much better than at home. A person who has gone many miles from home is prepared to undergo self-denial, which from habit at home might be more difficult to submit to.

Haig has discussed most interestingly the effects of meats which contain uric acid. He argues that when we are dealing with a disease in the causation of whose symptoms uric acid plays so large a part it is our duty to know the quantity of uric acid in the food that we consume. He does not differ from other observers in believing that the excess of uric acid is due to deficient excretion rather than excessive secretion or ingestion, but he found that matters were made worse by additional quantities of uric acid taken with the food.

Drugs.—Of the drugs that have been vaunted as specifics for gout the latest to engage our attention is piperazin. Its value, like most of its predecessors, is derived from its function as a uric-acid solvent, but this very argument is refuted in the same manner in which it is derived.

Sir William Roberts showed that piperazin solution in blood-serum of a strength greater than could possibly occur in the body had absolutely no effect on the solubility of urates. Disinterested clinical reports are not yet obtainable in sufficient numbers to form a judgment. We must not give too much weight to Sir William Roberts's experiments, because we have reports from Germany in which Biesenthal shows that in the gout produced in animals by the use of chromic acid uratic deposits were prevented by the use of piperazin. In the conduct of these experiments a scientific method seems to have been pursued. Two animals were subjected to injections of chromic acid for five weeks; one was given piperazin daily; the other was kept under identical conditions but received no treatment. The tissues of the latter were filled with copious deposits of uric acid, those of the former were free. It is not at all certain that this artificial disease produced in animals is identical with true gout, but it would seem that the weight of this evidence was at least equal to that of the English experiments. We must make our final appeal to clinical experience, that source from which it is so difficult to get a positive answer.

The use of salicylate of soda as an uric-acid solvent is gradually becoming popular, independent of any theoretical indication drawn from similarity of gout to rheumatism. There is still an impression on the part of some observers that rheumatism and gout have a close relationship to each other. This is being strengthened in some quarters by the use of the same drugs with some success in the treatment of both. Haig found by actual observation that salicylate of soda increases the excretion of uric acid. Phosphate of soda would seem to be a rational drug to use. The use of colchicum in chronic gout does not receive much support.

J. Mortimer Granville recommends the persistent internal use of iodine upon the belief that it is capable

of chemically uniting with excess of soda, detaching it from its combination with uric acid, and thereby rendering the resulting iodide of sodium and uric acid more soluble and easy of elimination. He also recommends lithium as a solvent.

The number of remedies for gout has always been very large. The great comic poet Lucian devotes many stanzas of his comedy "Podagra" to an enumeration of the remedies in use in his time. The opinion among physicians of the best judgment has remained, since the time of Lucian, that most reliance must be placed upon hygienic treatment.

Conclusion.—We have diseases affecting particular organs of the body. We have also diseases which affect the body as a whole. It is the dream of some enthusiasts that every morbid condition will some time be explainable by bacteriology, but, large as is the field of biology in explaining all infectious and most acute diseases, still we must allow to chemistry a place in the causation of nutritive and many chronic conditions. We may think of the human body as a most wonderful chemical laboratory. We grant to the stomach its title of chemist, but there are many other chemists in the body. The chemical machinery of the body is not perfectly apparent to the superficial observer, because, after all the other members had been placed in the situations best suited for their work, the chemical organs were fitted in wherever they would go. The circulation is the medium through which the chemistry of the body is carried on, and its perfected product is a pure blood. If you have ever examined large chemical works which have as a product a single material you will find the construction of the body has been imitated. Starting at one place, the raw material is reduced to a solution; then this is conducted to the next apartment, where something is added or taken away from it; from there to another apartment, and so on throughout the whole works, each department performing some function in connection with the circulating material until finally it comes out a complete product. In the same way in the body the blood circulates through a great many different organs, whose function is to modify in some way its chemistry. As the blood in its office of nutrition of the body must circulate everywhere, it has been possible to locate these organs in the most unexpected places. This renders our study of the chemistry of nutrition very difficult. The importance of the liver we have known for a very long time. Of the spleen we know much less; of late our attention has been concentrated upon the thyroid gland. The marrow of the bones we think has an important function. There are a thousand other laboratory assistants in the lymphatics. All this great system is presided over by the chemist-in-chief, the nervous system. It would be just as idle to deny the importance of the controlling function of the nervous system as it would be in chemical works to detract from the importance of the chemist-in-chief, who alone keeps the whole establishment working harmoniously. With this picture in our minds of the human body as a laboratory, we are in a position to appreciate the nature of that class of diseases of which gout is one, and to understand why now one organ, now another, and finally the nervous system itself, has been indicted as the inciter of the difficulty.

No satisfactory description of chronic diseases has ever been written. The reason may be that diseases are not, as the indexes of our books think, distinct entities. One chronic disease gradually fades into another, or two run along side by side, intermingling their symptoms. To the honor of medicine it may be said that many men have arisen who sought medical truth for truth's sake, but it has been unfortunate that no one has been able through the vehicle of language to convey the best qualities of this knowledge to others. The great Sydenham said of himself: "It is my nature to think where others read; to ask less whether the world agrees with me, than whether I agree with truth; and to hold cheap the rumor and applause of the multitude."

The progress of medical truth and the cultivation of the power of conveying it to others will be much advanced when all can say that it was their nature to think, and their profound desire that the conclusions of their thoughts should coincide absolutely with truth. An appreciation of chronic diseases in all their bearings upon the life and happiness of the patient is only obtained by much thought and observation. The beginner looks with too much anxiety, the older man with too much philosophy at chronic conditions. The beginner has not assimilated the important law by which, physically and mentally, men adapt themselves to the inevitable. The older man may have gone too far, and has flagged in the attempt to modify what he knows he cannot cure. Another thing that has made the description of chronic diseases deviate from the average truth as seen in practice is that most writing is done from the standpoint of hospital practice, to the neglect of the experience of private work. This is especially unfortunate in the case of gout. Again, it is true in these days, at least, that nearly all young men write, and nearly all old ones are silent. For this reason it would seem that the cause of truth will be advanced if the conceptions of gout, as presented in this paper, can be discussed and criticised by those of the maturest judgment.

36 West Thirty-fifth Street.

OBSERVATIONS UPON MULTIPLE SURGICAL OPERATIONS, WITH A REPORT OF A CASE IN WHICH NINE OPERATIONS WERE PERFORMED AT ONE SITTING.[1]

By GEORGE R. FOWLER, M.D.,

Surgeon to St Mary's Hospital, and to the Methodist Episcopal Hospital, Brooklyn, N. Y.

Before the introduction of anæsthetics into surgical practice practitioners of our art cultivated rapidity of operating as a *sine qua non* of professional success. Surgeons who planned boldly and executed with rapidity and dexterity were always in demand in the days when the cries and groans of the patient were so loud as to drown the voice of the operator as he gave directions to his assistants. Every second saved, under these circumstances, was a distinct gain to the patient, and indirectly to the operator himself, if he chanced to be a man of heart in the sentimental sense, as well as a man of nerve in the professional sense. No wonder, then, that operations were carried out in a typical manner only, as carefully planned, all other considerations being made subservient to the one and great desideratum, namely, that of completing the operation as speedily as possible, thus relieving the patient of physical torture and the surgeon of mental strain.

With the advent of anæsthetics came the introduction of more extensive and elaborate procedures in operative work, until to-day it is quite as necessary, in the patient's best interests, to cultivate combined rapidity and manual skill as in the days when routine operative work included but little more than trephining a skull, amputating a limb, or cutting for stone; this notwithstanding the fact that the patient, at the present day, is entirely oblivious of pain or the startling character of his surroundings. Not only have the older operations been elaborated upon, and new and more extensive ones introduced, but occasions not infrequently arise where several operations are performed upon the same patient at one sitting. The justifiability of the introduction of more than one operation at a single sitting rests, first, upon the advantages to be gained by this course in the individual case; second, upon the

[1] Read before the Brooklyn Surgical Society, December 6, 1894.

condition of the patient at the time of the operation, particularly with reference to his powers of resistance to shock and hemorrhage, together with the dangers of the anæsthetic; and third, to a proper estimate of his reparative powers. Further, the number, character, and extent of the proposed operations are to be taken into account, as well as the resistance to infection and tolerance of interference of the parts operated upon.

All of these must be carefully weighed and a decision arrived at by the person who is held responsible for the patient's welfare, namely, the operating surgeon himself. Each case is to be carefully studied in all its bearings, and above all things the element of time taken into account. This will involve considerations of facilities for performing the work, the familiarity of the operator with the proposed operations, his ability to execute them in a rapid and at the same time safe manner, and last, but not least, the availability of skilled assistants or coworkers who are familiar with his methods.

Preliminary Operations.—These may be defined, 1, as those which are of a precautionary nature, and are designed to prevent dangerous complications of the operative procedure; and 2, those which are intended to facilitate the steps of the main operation. Of the first class may be mentioned ligature of important vessels as a preliminary step in the removal of certain tumors, excision of the tongue, etc. In the second class are included such operations as temporary osteoplastic resection of the upper jaw in the removal of growths from the naso-pharyngeal space, and tenotomy as an aid in the reduction of the fragments in fractures, and in certain dislocations as well.

Simultaneous Operations.—In crush injuries in which more than one member is involved, requiring double amputation, or an amputation and a resection; in cases of injury to the head, in which trephining is necessary in addition to either an amputation or a resection, or both, simultaneous operations may be indicated. In addition to these, necrosis of the bones of both legs or of other diseased conditions occurring in parts sufficiently remote from each other to permit two operators to work at the same time, constitute examples of the indications for this class of multiple operations. In the patient's own interests, and where the conditions will permit of it, the operation should be so organized, under these circumstances, as to permit of simultaneous procedures at the hands of two operators and two corps of assistants. This is particularly true of emergency cases, where the operations are entered upon during the primary period, and where the patient's life may depend upon the prompt removal of the injured parts, in order to permit of the arrest of hemorrhage or to arrest progressive shock from the presence of crushed and mangled nerve-trunks.

Coincidental Operations.—In this classification may be included those cases in which the patient, suffering perhaps from a condition the painful or threatening character of which renders the performance of an operation of necessity, may request that some minor diseased condition, such, for instance, as an atheroma of the scalp, be corrected by the operator at the same time. Usually the minor affection receives attention after the more important operation has been completed, the operator not deeming the former to be of sufficient importance to require a simultaneous operation, and reserving the judgment as to the propriety of continuing the work or otherwise, according to the patient's condition at the close of the first.

In this class may also be included operations upon the cervix uteri and perineum in which the effects of the injuries for which the operations are required are separate and distinct. For instance, the perineorrhaphy may be demanded by failure on the part of the patient to retain the contents of the rectum as a result of involvement of the anal sphincters in the laceration, while trachelorrhaphy may be indicated by the presence of an eroded condition of the cervical tear, and cervical and corporeal hyperplasia, etc.

Supplementary Operations.—These may be defined as operative procedures which are employed to fill out or complete a typical operation already designed or carried out in order to more completely fulfil the purposes of the original operation, as, for instance, when the pectoral muscles and subclavicular and axillary lymphatic glands are removed as a precautionary measure in addition to typical amputation of the breast for carcinoma; or that which is added to an operation for the purpose of supplying a defect caused by, or to repair an accidental injury occurring in the course of the original operation. As familiar instances of the last two may be mentioned the addition of skin-grafting to an operation for the removal of an extensive but superficial epithelial carcinoma; and enterorrhaphy to repair an accidentally inflicted injury to the intestine in the course of an abdominal section.

In addition to these there is a class of cases in which several operative procedures of an entirely different character are designed to effect the same object and are employed with the design or expectation that one will be supplementary or complementary to the other. Most conspicuous in this class are those cases in which, as the result of accidents occurring during parturition, a condition of affairs confronts the surgeon in which various pathological states are in existence at the same time, all of which are traceable to the same primary cause. Here, however carefully each individual operation may be planned, failure to achieve the principal object in view may ensue because the operator stopped short of a supplemental procedure which was not thought necessary at the time, or which was postponed for future performance.

Further, certain precautionary operations are to be employed under conditions requiring the same, the necessity for their performance arising in connection with an already planned and executed operation. Instances of these may be cited in the necessity for entero-fixation following the successful release of a volvulus, and the removal of the vermiform appendix, the right tube and ovary having been removed, in order to guard against the occurrence of vicious adhesions between this organ and the stump of the latter.

Finally, in the course of an operation it may happen that the indications for simultaneous, coincident, and supplementary procedures are developed as the operation progresses. Here the rapid judgment of the surgeon must be called into play, for to hesitate long under these circumstances to discuss the matter pro and con is to permit the most important of all advantages, that of time, to be lost. In case the supplementary procedure is made necessary by the accidental infliction of an injury, particularly if the part injured be any portion of the intestinal canal, there can be no question as to the course to be pursued. The part must be repaired at once, even if the time occupied in accomplishing this involves abandoning of the originally planned operation. Next in importance is to be considered the dealing with conditions more or less likely to lead to serious complications in the future, such as the closing of accidental rents in the omentum, the covering of raw surfaces intra-peritoneally located, by means of adjoining and healthy serosa, etc.

Instances might be cited almost *ad infinitum* of conditions which either require a multiplicity of operations at one sitting, or in which these may be added with advantage. The following case, the record of which is taken from the report of my service at the Methodist Episcopal Hospital, is offered in illustration of a class coming under the surgeon's care in which multiple operative procedures are rather frequently required:

Laceration of Perineum and Cervix Uteri—Cystocele—Rectocele—Chronic Metritis and Endometritis—Procedentia Uteri—Hypertrophic Elongation of Cervix—Cystic Degeneration of Ovaries.—Hospital No. 4,592.

service No. 1,609. Clara P——, aged thirty-five, married. Admitted January 5, 1893. This patient was married two years prior to her present admission to the hospital, and nine months thereafter, without any apparent untoward occurrences in the course of her pregnancy, she gave birth to a seven-months' child. She is a Swede, and speaks but very little English. This, together with the fact that she is not a very intelligent person at best, renders it exceedingly difficult to obtain a clear account as to her menstrual and other history prior to her marriage, or the events which followed her first delivery.

Three months ago she entered the hospital for confinement with her second child. She was cared for in the Medical Division. At this time there was found protruding from the vulva a large, red, œdematous, and eroded mass, which upon examination proved to be the cervix of the pregnant uterus, with bilateral laceration. The entire perineal body was absent, as a result of an extensive rupture of this portion of the floor of the pelvis during her first labor. The mass was replaced within the vagina and retained by a compress and T-binder, the patient maintaining the dorsal decubitus for one month (until delivery), the œdematous cervix becoming reduced to one-half of its original size by this treatment. Her labor was a long and tedious one, the head refusing to engage in the superior strait, and was finally terminated by a high forceps operation. The patient made a good recovery, and six weeks afterward was admitted to the surgical service for operative treatment.

Examination at this time revealed the following: The patient is thin and spare, but otherwise in good general condition. There is found protruding from the vulva a greatly elongated cervix with bilateral laceration, and a portion of the body of the uterus as well. There is no trace of a perineal body. Upon lifting the mass from the posterior vaginal wall the latter, greatly thinned, bulges forward in the shape of a large rectocele. The anterior vaginal wall is dragged forward and downward, and a portion of the bladder wall as well as the entire length of the urethra, is prolapsed. The uterine cavity measures three and a half inches, including the hypertrophic elongation of the cervix. The endometrium gives a soft and velvety sensation when explored with the sound, and the withdrawal of the latter is followed by slight hemorrhage. Both urination and defecation are accompanied with great distress.

Operation.—Ether. Patient in lithotomy position.

1. *Curettage.*—The cervical canal was thoroughly dilated and the diseased and softened endometrium curetted away. This bled freely until the entire surface had been gone over, after which irrigation with borosalicylic solution and tamponing with iodoform gauze served to arrest the hemorrhage.

2. *Amputation of the Cervix Uteri.*—The posterior lip was seized with double tenaculum forceps and a transverse incision made upon the mucous membrane surface close to the bottom or angles of the bilateral laceration. This incision took an upward and backward direction, its depth terminating about half-way through the thickness of the lip. A second incision was made upon the vaginal surface of the posterior lip, the latter being elevated by the double tenaculum forceps for that purpose. This incision was carried into the depths of the lip in an upward and forward direction until it joined the first incision, thus removing a wedge-shaped segment of the posterior lip, with its apex above and its base below. A silk suture was passed through both flaps at the site of the intended cervical canal and utilized for depressing the posterior lip, while the same procedure was carried out upon the anterior lip.

3. *Trachelorrhaphy.*—The cervix being steadied by means of the temporary sutures passed through the lips of the cervix, the commissures of the laceration, which were filled with a hard fibrous mass of cicatrix, were cleared by removing therefrom conical segments with their apices divided upward. The mucous membrane flap of each lip was then trimmed away so as to leave a proper width for the cervical canal, and the parts drawn together with chromocized catgut sutures. These were passed in such a manner as to close the deep angles from which the cicatricial masses were removed at the commissures of the laceration, and at the same time approximate the raw surfaces of the flaps left by the removal of the wedge-shaped pieces from the anterior and posterior lips. This being accomplished the temporary silk sutures were withdrawn.

4. *Anterior Elytrorrhaphy.* — A triangular-shaped flap was marked out upon the anterior vaginal wall, its apex downward, its base upward. The incision marking the outline of this flap was carried through the mucous membrane of the vagina only. The portion of the vagina included within the limits of this incision were then grasped by means of a strong curved fixation forceps, and the entire flap removed by snipping with the points of scissors from the edges toward the centre. The resulting denuded surface was then sutured by a running catgut chromocized suture, the apex of the triangle being first closed, and then the angles of the base each in turn, the resulting suture lines uniting so as to form a Y.

5. *Colpo-perineoplasty by Flap-splitting.*—A semicircular incision was made with sharp-pointed curved scissors, following the line of the posterior commissure of the vulva at the point of juncture of the mucous membrane of the vagina and the skin covering of the perineum. The mucous membrane of the posterior vaginal wall was separated from the submucous connective tissue by the scalpel for a short distance, and then rapidly separated from the wall of the rectum by means of blunt scissors, this being facilitated by occasional snips where the connective tissue was dense; the greater portion of this separation was effected bluntly, however. The separation was carried in an upward and posterior direction to a point beyond the original limits of the perineal body, and laterally so as to thoroughly expose the retracted remains of its muscular structures. The vaginal flap was now grasped at its middle and held out of the way, while the resulting gap was closed in the following manner: A strand of silkworm-gut was armed at each end with a large strongly curved Hagedorn needle. The remains of the perineal body, not including the skin, were then transfixed on either side and the first loop of the suture made to approximate these. The needles were then reversed as regards position, that which passed through the right side being carried to the left, and *vice versa*, and passed through the skin. This constitutes the application of the crossed suture to perineorrhaphy. The entire gap was closed in this manner, the ends of the silkworm-gut being tied over so as to approximate the skin edges, the loop first passed bringing together the deeper parts.[1] The stitches were passed in the following order: First, the one at the site of the centre of the retracted perineal muscles; second, the one below, and third, the one above the centre. Then the anal extremity of the gap was closed from below upward. The mucous membrane flap, which up to this time had been held upward and forward by a tenaculum in the hands of an assistant, was allowed to fall back, its raw edge was hemmed by a catgut suture, and the vagina was packed with zinc oxide gauze.

6. *Double Oöphoro-salpingectomy.* — Trendelenburg position. The abdomen was opened in the median line by a six-inch incision, the fundus uteri was identified, and each tube and ovary brought in turn to the abdominal opening, ligated close to the uterus by the Stafford knot, and excised. Just as the peritoneum

[1] I have since modified this method by pairing the crossed sutures and tying the paired ends over pieces of rather thick-walled drainage tubing, somewhat after the manner of the quill suture of the older surgeons.

was being divided in the median incision the patient, through an error on the part of the anæsthetizer, gave a convulsive cough, and a knuckle of intestine was forced between the blades of the scissors and injured. It was a matter of great importance that the damage thus inflicted should be repaired at once.

7. *Enterorrhaphy.*—The parts about the injured loop of intestine were immediately covered with sterilized compresses, my assistant, Dr. Delatour, at the same time grasping the loop above and below the point of injury, to prevent the escape of the contents of the intestine into the abdominal cavity. A fine cambric needle, armed with the finest iron-dyed aseptic silk, was employed, and typical Lembert suture of the serous covering of the intestine performed, by the running "over-and-over" stitch. A mixture of compound tincture of benzoin sterilized by mercuric chloride in the proportion of 1 to 1,000, and to which ten per cent. of iodoform had been added, was pencilled along the line of intestinal suture. The operation of double oöphorosalpingectomy was then proceeded with, as above detailed. As the right tube and ovary were cut away the vermiform appendix came into view. It was fully four and a half inches long, and contained three separate enteroliths. The direction of the organ was downward and inward, and in a position to form adhesions to the stump of the right tube, or become involved in any adhesive inflammation which might subsequently occur. It was therefore decided to remove the appendix.

8. *Appendicectomy.*—The organ was seized by its tip, brought out of the abdominal opening, and a double ligature of catgut passed through the meso-appendix at its base. One ligature was made to encircle the appendix after reflecting a cuff of the serosa of the same, the other the mesentery. These were tied separately, and the appendix and its mesentery amputated. The stump of the appendix was sterilized in its interior beyond the ligature by the thermo-cautery heated to a dull or cherry red; then, together with the stump of the mesentery, it was buried in a furrow of the cæcum made to receive it, and secured there by a continuous Lembert suture of fine silk. The sterilized mixture of iodoform and compound tincture of benzoin was applied along this suture line.

9. *Gastro-hysteropexy.*—This was decided upon when, after amputation of the cervix and the performance of the anterior elytrorrhaphy and the colpo-perineoplasty, it was found that without further support the uterus still came down to the vulvar orifice. It was with this in view that the abdomen was opened. The discovery of cystic degenerative disease of both ovaries at once determined the particular procedure to be adopted in accomplishing this. The stumps resulting from the excision of the tubes and ovaries were utilized for this purpose. These were placed with their raw surfaces applied to the parietal peritoneum, one to either side of the median abdominal wound, and there secured by four sutures of fine silk. Additional sutures were passed through the serous covering of the fundus of the uterus and the parietal peritoneum.

The abdominal wound was now closed by means of silkworm-gut crossed sutures, one of which was passed so as to include the peritoneum of the fundus at its anterior aspect, in order to secure adhesions at this point and thus prevent a gap in a locality where a knuckle of intestine could subsequently slip through and become strangulated. Dressings of heat-sterilized zinc oxide gauze were placed next to the abdominal wound; compresses of gauze wrung out of mercuric chloride solution, and a layer of sterilized non-absorbent cotton were next applied. These were secured in position by a snugly pinned abdominal binder.

The following note is taken from the operation-book at the hospital: Clara P——, January 13, 1894. Anæsthetic began, 2.43 P.M.; anæsthesia established, 2.58 P.M.; anæsthetic stopped, 4.15 P.M.; amount of ether used, eleven ounces.

No attempt was made to operate "against time." Counting the actual time of the operation as extending from the establishment of the anæsthetic to the stopping of the same, just seventy-seven minutes were consumed. The time occupied in bringing the patient from the anæsthetizing-room and arranging her upon the table may fairly be considered as balancing whatever was done for her after the anæsthetic was stopped.

This patient's recovery was final and complete. The healing of the abdominal wound was complicated by a stitch abscess; this gave rise to symptoms which disappeared upon complete evacuation, careful curetting, and the use of a fifteen-volume solution of the peroxide of hydrogen. She was not permitted to assume the erect position for eight weeks, in order to secure stability of the adhesions at the site of the hysteropexy, as well as solidity of the pelvic floor. Her stay in the hospital covered a period of eighty-one days; twenty-four days of this time, however, being occupied in keeping her under observation, and to permit her to regain her strength sufficiently to resume the duties of her household.

CLINICAL SYMPTOMS DUE TO CHRONIC PERIVESICAL INFLAMMATION.[1]

By EUGENE FULLER, M.D.,

NEW YORK.

Perivesical inflammation, or, as it has been aptly called, pericystitis, has received some attention of late, chiefly, however, from a pathological and an etiological stand-point. Before coming to the main purpose of this paper it has seemed well to briefly review the literature, most of which has been directed toward the study of inflammations specially involving the space of Retzius. This space has become of much surgical importance owing to the frequency of the suprapubic operation. J. Englisch,[2] of Vienna, has presented a very complete article on idiopathic inflammation of the perivesical connective tissue in the space of Retzius. Guyon,[3] of Paris, one on fluids either inflammatory or extravasated in this space; and E. Martin,[4] of Geneva, one on cases of idiopathic suppuration in this part. P. Thorndike,[5] of Boston, and E. Martin,[6] of Philadelphia, also have each reported an instance or so of such inflammations. Noel Hallé,[7] of Paris, however, is the only one who has in a general way considered the subject of chronic perivesical inflammation. This author, in his article entitled Pericystitis, has excluded from his consideration acute phlegmonous inflammations of the space of Retzius, the special topic of the other writers just quoted. Hallé's article deals almost exclusively with the pathology of the subject. From this literature we are taught that occasionally the space of Retzius is invaded by inflammation, usually apparently idiopathic in character, though at times traumatic or due to some special agency. At first, when such inflammation is slight in extent, there are, as a rule, no subjective symptoms aside from febrile ones, except suprapubic tenderness. As the area of inflammation increases, however, it forces its way between the recti muscles, and then burrows beneath the fascia external to those muscles, generally in the direction of the umbilicus, though Martin, of Philadelphia, reports a case where it burrowed laterally and downward so as to simulate an inguinal hernia. When this burrowing is represented by a phlegmonous inflammation, then a hard boggy tumor appears in the suprapubic region. When, on the other hand, it is

fluid, being either purulent or urinous, then a fluctuating tumor presents itself, which may, as Guyon has emphasized, be easily mistaken for an over-distended bladder. With this condition, however, there are associated no special vesical symptoms. Hallé shows that the perivesical tissues, in the same well-known manner as the perirenal tissues, can be and often are involved by chronic inflammation. The origin of the inflammatory agent in these cases may be vesical or from some near-by organ (*i.e.*, intestinal or genital). The character of the inflammation is sclerous, adiposclerous, or suppurative. When the bladder is the origin of the inflammation the process reaches the perivesical tissues by directly penetrating the bladder walls. Gonorrhœa, tubercle, neoplasms, germ infection, and traumatisms are causes for such vesical inflammations. Generally all the surrounding perivesical tissues are not involved by inflammation, the tissues in connection with the summit and base of the bladder only being invaded, though occasionally the surrounding inflammation may be general.

Hallé reached his conclusions from extensive post-mortem study, and, as in most instances where lesions of vesical origin were discovered, there had been no bladder symptoms complained of during life, he rightly concluded that these lesions generally gave rise to no subjective symptoms.

The object of this paper is to take up the clinical side of this question, heretofore but little discussed, and to show that there does exist a class of cases, rare to be sure, representative of this condition, in which the clinical symptoms are most marked. It is only those instances, however, in which the pathological process completely, or in great measure, involves the entire extent of the surrounding perivesical connective tissue that present clinical symptoms. In such cases the symptoms presented are due to the fact that the pathological lesions rob the bladder of its expansive quality and force it to remain in a state of permanent contraction. The denser the perivesical inflammation, the more contracted the bladder and the more rigid its walls, so that in extreme instances the vesical capacity is almost nil. When but a fraction of the area of the bladder walls is involved, then the portion left free to act undergoes a certain amount of compensatory hypertrophy of its muscular walls, thus enabling the bladder to exercise its expansive and contractive functions, and consequently no subjective symptoms result. The condition of localized perivesical inflammation always follows to a greater or less extent the operation of suprapubic cystotomy, the anterior superior portion of the bladder wall being bound to the parietal abdominal structures, and yet this condition, being circumscribed, in no way interferes with the vesical function.

In the majority of these cases presenting subjective symptoms the surgeon is liable to find a history of severe gonorrhœal cystitis, occurring perhaps years previously in a subject lymphatic, or with tubercular tendencies; or less commonly there may have been no gonorrhœal element in the cystitis, it having been tubercular, infective, or traumatic. In some cases there may be no inflammatory vesical history, as in those in which the pericystitis is caused by a neoplasm, or—and this is very rare—in those in which the inflammatory focus is independent of the bladder, being connected with some near-by organ. The urine voided may be purulent and loaded with inflammatory elements such as one would expect to find associated with chronic cystitis, or it may be clear and free from such elements. This latter condition of the urine may be found in those cases in which a previous cystitis has ended in resolution as far as the vesical mucous membrane and the submucous tissues are concerned, and in those cases in which there has never been inflammation of the vesical mucous membrane.

Symptoms in connection with urination are constant and most marked. In all cases there is an inability to hold the urine at all times for more than a short period, the quantity voided at a given instance being small, thus corresponding with the capacity of the bladder. In cases where the lesions are severe the capacity of the bladder may be so small as to allow of no accumulation of urine, vesical incontinence resulting.

There is ordinarily little pain associated with such frequent urinary acts, and oftentimes it is entirely absent in case no cystitis is present. There is no marked urgency preceding the act nor tenesmus after it. If an individual so affected is called upon to explain the sensations which he experiences forcing him to urinate, he is apt to state that there is a marked absence of the normal sensations, the urine generally coming away with little warning. In the milder grades of cases, where the urinary act is simply frequent, active exercise tends to increase the frequency, so that at such times incontinence may result, requiring the wearing of a urinal. Pain in the suprapubic region, in the lower back, and in the perineal region, may be complained of. Such pain is generally described as dull in character and intensified by long standing or much physical exertion. Of course, in cases where cystitis coexists, the pains incident to that affection are also present.

If now the attempt is made to pass a catheter, the instrument, in case there is no organic stricture, will pass perfectly easily into the bladder, encountering but little spasmodic resistance in the membranous urethra and without causing the patient any special disagreeable sensations. A very small amount of urine, perhaps only a few drops, will flow from the catheter after it has entered the bladder. If then an attempt be made to inject the bladder through the catheter it will be found impossible to do so more than to a very moderate degree. If forced attempts be made to inject fluid the result will be a prompt and strong return flow of the fluid, generally along the urethra outside the catheter, thus tending in a marked manner to force out the instrument. This return flow of fluid is, however, associated with little or no sensations of vesical tenesmus. If we consider a moment we see how much this simple procedure with the catheter teaches. In the first place it shows that the frequency of urination is not caused by an inflamed or neurotic vesical neck, otherwise much tenderness and spasmodic resistance would have been revealed by the passage through the membraneous urethra of the instrument. In the second place, that the frequency or incontinence is not due to paralysis more or less complete, in which case little or no resistance would have been offered on attempting vesical distention. In the third place, that the urinary symptoms are not due to vesical distention and overflow, since the catheter found the bladder empty. It might be said with reason that a general neurotic or hysterical condition could stimulate these conditions found by the catheter, and so they could. In fact, the only way to rule out these latter conditions from the diagnosis is to administer enough of an anæsthetic to occasion muscular relaxation; then if the case is hysterical or neurotic the bladder can be distended with fluid to its normal capacity without offering any resistance. If, however, the case is one of chronic perivesical inflammation, then the resistance offered to the injection of fluid persists, being affected little, if at all, by the administration of the anæsthetic.

In investigating these cases resort should be had to the rectal feel and to bi-manual palpation between the rectum and hypogastrium. The result derived from these procedures may be negative or it may reveal more or less abnormal resistance and induration in connection with the tissues composing the vesical region. Nothing in the way of positive evidence, however, can, as a rule, be derived from these manipulations.

Cases representative of this disease cannot be cured. Those of them, however, originating from a cystitis

can in some instances be more or less benefited by prolonged and persistent treatment. If the patient is more or less strumous or tubercular, hygienic methods, combined with cod-liver oil, hypophosphites, etc., help. For local treatment, bladder gymnastics so-called (Daggett,[1] of Buffalo, has written on this form of treatment) seem to be of some benefit, though the good derived thereby is generally but temporary. This form of treatment consists in the regular stretching of the bladder walls by the injection into it under regulated pressure of a warm antiseptic fluid.

The following cases which have come under my observation will be cited as illustrative instances :

Case I.—A man, aged thirty, first came under observation six years ago. At that time he was suffering from frequent urgent and painful urination. His trouble had originated in a gonorrhœa, which had extended to the bladder. Shortly before being seen he had been confined to his bed a month owing to the vesical inflammation. There had been at that time much suprapubic pain, some of which still persisted. His urine was loaded with pus, foul smelling, ammoniacal, and occasionally somewhat bloody. There was no stricture. He had no marked tubercular element in his history, although he had never been very strong and had some strumous evidences. At that time Dr. Keyes performed perineal section in order to establish vesical rest and drainage. After the section had been made the finger was introduced into the bladder. The vesical walls were found to be lined in numerous places with areas of granulations marking the site of previous active ulcerations. In a number of places phosphatic crusts were found adhering to the granulations. The interior of the bladder was then thoroughly curetted and a large perineal drainage-tube inserted. The patient soon became very comfortable with his tube in, and the urine passing through it became sweet and but slightly purulent. After a time the tube was removed, the character of the urine continued to improve and after a time it became clear and normal. The urination was no longer painful, still it continued almost as frequent as before the operation. The patient gained flesh and strength. After a hard day's work, however, a little suprapubic pain would always return, together with some increase in the frequency of urination. Now after six years the patient still remains in this same condition of frequent urination. His bladder can be but moderately distended and the catheter shows the symptoms which have just been described, indicative of pericystitis, to exist. He has tried vesical distention at regular intervals, vesical gymnastics so-called. This treatment has been followed by improvement, which, however, has been found to be but temporary, the original contracted state of the bladder returning as before shortly after its cessation.

Case II.—A man, twenty-eight years of age, was first seen two years ago by Dr. Keyes, complaining of urgent urination every one and one-half to two hours night and day. All this followed a gonorrhœa, which he had contracted six or eight months previously. There was much pus in the urine, and much vesical epithelia. No stricture. Various forms of local treatment had been tried without avail. Rectal examination and bi-manual palpation showed considerable induration of the pelvic tissues. Perineal section was performed to cure the cystitis by establishing drainage. This was successful, as after convalescence from the operation the urine became perfectly clear. The perineal wound, however, healed slowly, a slight fistula persisting. The patient became strong and gained twenty pounds in weight over that at the time of the operation. All localized painful sensations disappeared. The frequency of urination, however, gradually increased until incontinence and dribbling resulted, the bladder remaining in a state of permanent contraction. Now the patient goes about, leading an active life, wearing a urinal. The reason that the urinations gradually became more frequent after the cure of the cystitis is probably because the perivesical inflammation has gradually become more organized and fibrous as time goes on, thus leading to a firmer contraction of the bladder.

Case III.—An elderly man, sixty-five years of age, had always led an active life. No venereal history. For about a year off and on he had had severe attacks of pain in the pelvic region and had noticed that his acts of urination were gradually becoming more and more frequent day and night, though as a rule the attacks of pain which he had experienced seemed to have no special connection with the urination, except that after an active day's work he was more apt to have the attacks of pain and the frequency of urination was somewhat increased. He had been told that his trouble was due to an over-distended bladder, and a catheter had been passed a few weeks before the patient came under my observation. The report was, however, that when the catheter entered the bladder only a few drops of urine had been drawn off. Since that time pus had appeared in the urine together with occasionally blood, and the acts of urination had become very painful. All this was due, apparently, to the fact that the bladder had become infected by the catheter. When first seen by me, the patient's general condition was bad. Chloroform was given, and the bladder examined. It was found to be rigidly contracted, allowing of no expansion. The patient died about one week afterward, having been rendered in the meantime partially comfortable by the administration of opiates. A post-mortem examination showed the bladder to be involved by a cancer, which had apparently originated in the mucous membrane of the upper portion and had gradually extended over the whole viscus, associated with a marked amount of perivesical involvement. Back of the trigonum, the portion last involved, there was a vesical sacculus, made up of a hernial protuberance of the mucous membrane between the vesical muscular fibres. This portion of the bladder-wall evidently was the last to lose its vesical function of expansion and contraction. The sacculus had probably formed late in the progress of the disease as the result of vesical tenesmus, after the bladder had mostly ceased to functionate.

THE ETIOLOGY OF CHOREA.

By ARTHUR CONKLIN BRUSH, M.D.,

ASSISTANT VISITING NEUROLOGIST TO THE KINGS COUNTY HOSPITAL; NEUROLOGIST TO THE CENTRAL DISPENSARY.

The etiological factors of chorea, as usually given by authors, may be divided into three classes : toxic, reflex, and psychological ; but in an article upon this subject, published in the *American Journal of the Medical Sciences* for January, 1894, Professor Dana, of New York, defines chorea as a disease "primarily of the blood-vessels and blood, with secondary degeneration in the parenchymata due to some microbe or toxic substance or both." "The anatomical seat varies, but it is chiefly in the cortical or subcortical motor centres." Thus limiting the etiology to the toxic, and excluding all reflex and psychological causes.

As to the seat of the lesion and the changes found in some cases, there can be no question, but in the belief that they are always due to a toxic cause I cannot help feeling that Dr. Dana has taken too narrow a view of this subject.

That the toxic causes are the active factors in a large proportion of the cases cannot be for a moment denied. We have only to remember the pathology of malaria and rheumatism, and their etiological relationship to chorea, to admit its truth ; but a similar condition of vascular dilatation and parenchymatous degeneration would also follow, and has long been ascribed to abnormal activity of the cerebral cells, as the result of

long-continued irritation of some peripheral portion of the nervous system (reflex irritation), or to abnormal mental processes.

We know, although we are as yet unable to demonstrate by our present microscopical methods, that each discharge of force by a nerve-cell is accompanied by a change either in its chemical or molecular structure, and, if such discharges are too violent or too prolonged, parenchymatous degeneration occurs. This increased cell activity would also cause an increased vascularity of the parts. The effect of such long-continued peripheral irritation in producing chorea, as Gowers says, "cannot be denied;" and in an article on this subject in the MEDICAL RECORD for May 5, 1894, Dr. Ranney sums up this subject as follows: "That many cases of chronic chorea get well, and remain well, without the use of drugs, whenever the sources of pheripheral reflex irritation are removed." He then gives the histories of ten cases with ocular troubles as cured by their correction; but it is not to the reflex but to the third class, the psychological, that I wish to call attention.

The psychological causes of true chorea are always some marked and acute affect, which gives rise to that violent and inco-ordinate activity of the cells of the cerebral cortex which constitutes an emotion. The emotions which thus give rise to chorea are, as far as I have been able to ascertain, of a painful and depressing character. Of these fright is by far the most common.

To comprehend how an emotion can produce such a disease as chorea, it is necessary to briefly review a few facts concerning the anatomy and physiology of the cerebral cortex. Concepts are due to the association of the different cells which receive the impressions which constitute them, and trains of thought to the further associations of such groups unto larger ones, the stimulation of anyone of which calls the rest into activity; and, when such impressions are so marked as to force themselves upon our attention, and thus destroy our conscious selection of concepts—for but one train of thought can occupy the mind at a time—they constitute an affect.

The effect, then, of the affect which give rise to the emotion of fright, is to throw the sensory cells of the cerebrum into such violent action as to break up the regular lines of thought, rendering the conscious selections of concepts impossible, and all mental action is in this way for a time suspended. The disturbance of the sensory cells of the cerebral cortex also shows itself in the disturbance of their inhibitory power over the cells of the motor areas. In the milder grades this is not much disturbed; but, as the mind cannot originate voluntary movements, no motor discharges are sent out, and the patient stands like a statue.

If the emotional disturbance is more severe, it shows itself in an increase in the inhibitory influence which the cortical motor cells possess over the spinal; and the normal rhythmical discharges by which the latter keep up the muscular tone of the body are diminished, and general muscular relaxation takes place.

If the disturbance is still more severe, the inhibitory power of the cortical sensory cells over the motor may be destroyed and the latter allowed to discharge themselves, producing convulsive movements. This state of violent action on the part of the cells of the cortex is rapidly followed by the opposite one of exhaustion. Mental action is therefore weak and confused, and the weakening of the inhibitory control of the cerebral over the spinal motor centres shows itself by an increase in the rhythmical discharge, producing a general muscular tremor. This increase and subsequent weakening of the inhibitory influence of the cerebral cortex, also shows itself in the disturbance of other systems than the muscular.

The heart's action is at first retarded, and may even be arrested, and then rapid and often violent. Respiration is at first arrested, and then rapid and labored. Digestion is arrested, and the bowels thrown into a state of increased peristalsis. The urine is increased in amount. The disturbance of the vaso-motor system is shown by the pallor and increased perspiration. Such violent action on the part of the cells of the nervous centres may, as I have said, be followed by degenerative changes, and according to the nature and distribution of such changes we have a neurasthenia, epilepsy, hysteria, insanity, paralysis agitans, or chorea resulting.

The difference in the character of the disease produced is to be explained by the differences in the development of the nervous systems, by the inherited or acquired weaknesses, and by the character, intensity, and duration of the cause.

True chorea is a disease of late childhood or early adult life—a period in which the nerve-centres have been developed, but in which the normal exercise of function has not yet developed that controlling and co-ordinating influence of the mind by which we recognize the relative importance of the various concepts.

The normal irritability of the nerve-cells, as of the other cells of the body, gradually diminishes with age, and is greater in the female than in the male. It naturally follows, from such a condition as this, that the violent cell-action found in emotions is more easily excited at this age, while the want of exercise of the inhibitory functions over the lower centres and the greater irritability of the latter render them more liable to disturbance of their functions.

Muscular movements are the normal means by which we express our emotions, and are therefore most marked in those in whom, by want of development of judgment and reason, they are the least modified and controlled, as in animals, the lower classes, and in children. The normal muscular movements produced by emotions also bear a strong resemblance to those of chorea.

That chorea is a disease of cerebral origin is now so generally admitted that it seems hardly necessary to state the following facts, upon which the theory rests: That the movements cease during sleep, while they would be exaggerated, if of spinal origin, when the inhibitory cerebral influence is in abeyance. By the unilateral character of the disease, spinal disorders producing bilateral disorders. By the greater involvement of the arm, it being more habitually under the direct control of the mind than the leg.

Chorea may then be considered as primarily a disease of the cerebral cortex, involving most markedly the superficial layers, and manifesting itself by the loss of control which the second or sensory layers possess over the deep motor layers.

When the motor cells are not damaged, the movements produced will, through the normal association either inherited or acquired of these cells, take the form of purposeful movements from the stimulation of groups of associated muscles. When, however, the lesion extends to the motor cells, and by an unequal amount of damage breaks up this grouping of motor cells into associated groups, then we will have irregular contractions of individual or parts of muscles. As is well known, in organic disease of the brain the cells of the lower centres, from want of proper control over their nutrition—as in the motor ones, by allowing them to discharge themselves too frequently, from destruction of the inhibitory power or from over-stimulation, exhaustion is produced—may undergo secondary degeneration, and, as the result, we will no longer have the movements controlled by voluntary effort and continuing during sleep.

In support of this psychological theory of the causation of this disease, I offer the histories of the following cases:

CASE I.—E. D——, male, aged eighteen; United States; admitted to the Kings County Hospital April 3, 1894. He has acted queerly since childhood. Would frequently leave home for several weeks. In July, 1893, he received a severe fright from being

thrown from the seat of a truck. This was followed by a general muscular tremor which lasted some days, when a mild attack of his present trouble developed. He was arrested two days before admittance, and in court the next day it was noticed that he was extremely nervous, and in the next twenty-four hours he developed the present condition. There are extremely violent, irregular clonic spasms of the muscles of the limbs, trunk, neck, face, and tongue, causing the patient to throw himself violently about, and rendering restraint necessary to prevent injury to himself and others. Contractions are partially controlled for a moment by voluntary effort. Mind seems clear, but it is very difficult for him to communicate with others. He died of exhaustion at the end of three days.

Case II.—C. M——, aged thirteen, female; United States. Seen at the Central Dispensary April 6, 1893. Badly frightened by a dog one month ago. This was followed by twitching of the facial muscles, which extended to the left arm and leg. Frontal headache. There are marked irregular clonic spasms of the muscles of the affected limbs, with loss of power and inco-ordination. The spasms interfere with voluntary movements and cease during sleep.

Case III.—S. S——, male, aged thirteen; United States. Seen at the Central Dispensary May 23, 1893. Received a severe whipping three weeks ago, after which he gradually developed marked irregular clonic spasms of all the muscles of the body, limbs, neck, face, and tongue. There is also marked loss of power and inco-ordination, with fibrillary tremors. Movements much diminished during sleep.

Case IV.—M. L——, female, aged thirteen; United States. Seen at the Central Dispensary September 16, 1893. Frightened three weeks ago by a horse. Since then has had choreic movements of the left arm. There are fibrillary contractions of these muscles, with some loss of power and inco-ordination.

Case V.—A. O'C——, female, aged eight; United States. Seen at the Central Dispensary November 23, 1893. Neurotic family history. Always nervous and anæmic. Frightened by an epileptic four months ago. Since then has had constant frontal headache, with twitchings of right arm and leg, causing her to drop objects and stumble. No movements during sleep. There are slight, irregular, partial muscular contractions in limbs named, with loss of power and inco-ordination.

Case VI.—P. E——, male, aged nine; United States. Seen at the Central Dispensary May 5, 1894. Neurotic family history. Sister has hysterical hemiplegia. Badly frightened three weeks ago. A few days after which he began to have violent clonic, irregular spasms of the facial muscles; these have gradually extended to the neck, body, limbs, tongue, and probably the larynx. The contractions keep the whole body and limbs in irregular and violent motion. Movements much diminished during sleep.

Case VII.—J. R——, male, aged six; United States. Seen at the Central Dispensary June 2, 1894. Thrown from a horse three days ago. Since then there have been irregular contractions of the limbs, body, neck, and face, with some loss of power and inco-ordination. Movements cease during sleep.

Case VIII.—W. B——, male, aged fourteen; United States. Seen at the Central Dispensary June 23, 1894. Frightened by falling downstairs six weeks ago, which was followed by a marked general tremor, and at the end of five days he developed irregular muscular contractions in the right arm. Stumbles in walking and drops things. There is also well-marked inco-ordination in the right arm and leg.

Case IX.—A. W——, male, aged fourteen; United States. Seen in private practice March 10, 1894. Mother and sisters hysterical. Insanity in the father's family, and father very eccentric. The boy is bright, precocious, and easily exhausted. Bodily development very poor. Much depressed one month ago by failure to pass his examinations at school. He then developed intense restlessness and insomnia. This was followed by irregular contractions of the muscles in the right arm and leg. There are also fibrillary contractions in these muscles, with loss of power and inco-ordination. Contractions interfere with voluntary movements and cease during sleep.

Case X.—M. F——, female, aged fourteen; United States. Seen at the Central Dispensary July 10, 1894. Health always good up to two months ago, when she received a severe whipping, which was followed in a few days by twitching of the muscles of the face and right arm and leg. The spasms interfere with voluntary movements, causing her to drop things and stumble. They cease during sleep. There is some loss of power and inco-ordination on the right side.

Case XI.—M. F——, female, aged eleven; United States. Seen at the Central Dispensary July 17, 1894. Previous health good up to three months ago, when she fell down the cellar stairs. This was followed in a few days by twitching of the muscles of the face, right arm, and leg, causing her to stumble and drop things. Movements interfere with voluntary motions and cease during sleep. They consist of irregular clonic spasms of individual or groups of muscles, associated with fibrillary tremors, loss of power, and inco-ordination.

Case XII.—M. T——, aged nine; United States. Seen at the Central Dispensary August 4, 1894. Her brother had the same trouble. Her chorea followed within a few hours a whipping received at school about three years ago.

There are irregular spasmodic contractions of the muscles of the face, right arm, and leg. Drops objects and stumbles in walking. There is inco-ordination and increased reflexes on the right side. Movements continue, but are less marked, during sleep.

Case XIII.—M. B——, female, aged forty-six; English; widow. Admitted to the Kings County Hospital on August 25, 1894. Family and personal history negative. Two and a half years ago she fell through a window, breaking her clavicle and lacerating her scalp. Present trouble was noticed soon after her recovery, and has been growing gradually worse. At the present time there are violent clonic spasms of the muscles of the face and limbs, keeping the parts in constant irregular motion. Movements continue, but are less marked, during sleep.

Case XIV.—A. H——, female, aged fifteen; United States. Seen in Dr. C. F. Barber's clinic at the Eye and Ear Hospital, on September 28, 1894. She fell through a skylight two and a half years ago, landing on her feet. She was not injured, but much frightened. This was followed for some hours by a general tremor, most marked in the lower extremities. This was followed by more rhythmical clonic spasms, commencing in the feet and gradually involving the face and arms. There is also some inco-ordination, loss of power, and fibrillary contractions. Movements continue, but are less marked, during sleep.

Case XV.—F. P——, male, aged ten; United States. Seen at the Central Dispensary October 18, 1894. Badly frightened, four months ago, by being told as a joke one night that there were burglars in the house. Next day began to twitch in left arm, and rapidly developed his present condition. There are irregular, violent, clonic spasms of the muscles of limbs, body, neck, face, and tongue, associated with fibrillary tremor; also marked loss of power in muscles of left arm and leg. Movements cease at night.

We have here, then, the histories of fifteen cases of chorea in which the disease followed a condition of violent mental disturbance, and in fourteen of these fright was the exciting cause. Thirteen of the cases had enjoyed good health up to the time of the commencement of the disease, and in four only was there any previous personal or family neurotic history.

In eight cases the choreic movements seemed to have been almost continuous with the tremor due to the fright, while in the other five cases it occurred within from one to three days.

Of course it might be claimed that the bacteriological infection had already taken place in these cases, and that the emotion was only the exciting and not the real cause; but in such a condition we ought to have the disease following any emotional disturbance, instead of one whose expressive movement it so closely resembles, and one would naturally look, in the majority of the cases, for some preceding evidences of ill-health.

330 Lafayette Avenue.

A NEW TREATMENT OF SEMINAL WEAKNESS, WITH ESPECIAL REFERENCE TO SEXUAL NEURASTHENIA.

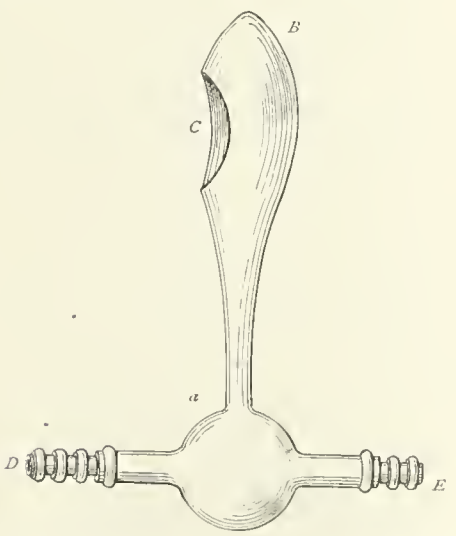
By ALFRED WIENER, M.D.,

Lecturer on Mental and Nervous Diseases at the New York Polyclinic; Visiting Physician to the Neurological Department of Mount Sinai Hospital Dispensary.

The success in the treatment of a number of cases of sexual neurasthenia with a therapeutic measure so simple and easy of application, both in my own practice and that of Dr. B. Sachs, has prompted me to make known my experiences in the same. I do not mean to imply by this article that I am making use of an entirely new method of treatment, but the application of this particular instrument, for this affection, in a manner which I will describe below, is at present entirely new.

It is found most applicable in cases of sexual neurasthenia attended with atonic impotence—patients in whom we find the prostatic portion of the urethra extremely hyperæsthetic; who complain of frequent seminal emissions, with more or less exhaustion; in whom the ejaculations are premature, and in whom the erections are imperfect and of short duration, so that intromission is sometimes impossible. In some the sexual desire is very much diminished, in others it is absent. Together with these local symptoms the patient complains of a number of neurasthenic symptoms, which, together with the former, help to make the patient a confirmed neurasthenic.

The accompanying cut is a very good representation of the instrument that I employ. It is similar to "Arzberger's" cooling apparatus, which is employed abroad in the treatment of hemorrhoids. The close proximity in which this can be applied to the prostatic portion of the urethra is what led me to make use of it for this purpose.



The instrument consists of a simple metallic cold-water coil, constructed in the shape of the letter T. The stem of the instrument (*a*) is narrower at the base than at the extremity, and is about one and one-half centimetres in thickness at its widest part, and one centimetre at the narrowest portion. It is bulbous at the extremity of the stem (*B*), and contains a slight concavity (*C*), just below the head of the instrument. Thus it easily adapts itself to the rectum, the concavity fitting itself very nicely to the prostatic portion of the urethra.[1] In regard to the application, the *modus operandi* is as follows: To the end (*D*) I attach a piece of rubber tubing five feet or less in length; I connect this with a rubber bag suspended immediately above the patient, who is most conveniently placed in the recumbent position with his back to the operator. To the other end I attach a piece of tubing long enough to extend from the couch on which the patient is reclining to a vessel on the floor. I now fill the bag with ice-water, and also put into it a piece of ice to keep the water at the same cold temperature. The instrument is then introduced into the rectum, well oiled, with the concavity toward the scrotum. The water, which has previously been held in check by a clamp arrangement on the rubber tubing, is now allowed to flow slowly through the apparatus, and into the pail on the floor.[2] Instead of renewing the water each time afresh, you can make use of that which flows into the pail on the floor, by merely pouring the same back into the rubber bag, and thus you will retain about an even temperature throughout the sitting. The application should last about ten to fifteen minutes, and should be repeated daily. The patient soon becomes accustomed to the use of the instrument, and learns very rapidly to apply it alone.

In order to demonstrate the usefulness and success obtained with this method of treatment, I append the histories of some typical cases.

Case I.—M. J——, aged twenty-four; married three years; occupation, grocer. Denies ever having had any venereal trouble. Admits that he was at one time addicted to masturbation. He never experienced any evil effects therefrom; but two and a half years after his marriage he noticed that although he still retained his sexual desires, he was no longer able to control his erections. Besides this he was suffering from five to six seminal emissions weekly. These left him in a very much exhausted condition, so that he was hardly able to attend to his business properly. A perfect erection of the penis was with him an utter impossibility. This condition, together with a slight catarrhal gastritis, combined to make this patient a very miserable man. In connection with the above he suffered from a variety of neurasthenic symptoms. An examination of the penis revealed a state of affairs that one most frequently finds in this class of cases. On passing a steel sound, No. 23 French, I encountered, about two and a half inches from the external meatus, an obstruction, which after a little patience in manipulation was easily overcome, and thus proved to be nothing else but a simple spasmodic stricture. As I entered the prostatic portion of the urethra the parts were so sensitive that the patient was unable to endure the pain of any further passage of the instrument, and I was compelled to desist from any further exploration that day. I sent the patient home, having prescribed for him a solution of the bromide of potash, containing twenty grains to the teaspoonful. This was to be taken one teaspoonful thrice daily, and he was to return to me in three days. I then examined his urethra with much better success, in that I was able to introduce the sound into the bladder. Nevertheless, I found the prostatic portion of the urethra extremely sensitive and hyperæsthetic. At first I advised the continuance of the potassium bromide. I suggested also the passage of the sound and psychro-

[1] Instrument and attachments can be obtained from O. Kalish's surgical and orthopedic department, 102 East Twenty-third Street, New York City, or can be made by any good surgical company.

[2] This is accomplished by means of a lead weight attached to the end of the tubing, and so constituted that it will allow the water to flow at any rapidity desired, while at the same time it prevents the tube from leaving the pail.

phore. These were to be passed alternately every third day during the first week, and every day during the second and third weeks. All sexual intercourse was interdicted; no stimulating drinks were allowed; and the patient was put upon a diet consisting of plain and easily digested food. At the end of three weeks a second examination was made, and the result was so discouraging that the patient would no longer submit to this method of treatment. I discontinued the use of the sound, psychrophore, and potassium bromide, and substituted instead the cold water through the rectum (rectal psychrophore). The result was astonishing. At the end of the first week improvement had already begun to set in. At the end of the fourth week I could pass a sound without any difficulty. The emissions had ceased entirely. I continued this treatment for two weeks longer, and advised the patient that if he continued to be more regular and temperate in his sexual relations hereafter, he need have no fear of a return of his former trouble.

Thus after six weeks of treatment with the rectal psychrophore, I discharged this patient as cured. It is now three years ago since I treated this man, and he tells me on inquiry that he never had a return of his old trouble, and that his genital organs are in perfect condition.

Case II.—A. C——, aged twenty-nine; unmarried; occupation, commission merchant. Had led, up to the time that I first saw him, a very dissipated life. He was having seminal emissions nightly. He was utterly unable to control an erection. His penis was cold and flabby. On attempting coition his ejaculation was premature. No pleasure was derived from the ejaculation. Patient suffered likewise from a number of cerebrosthenic and neurasthenic symptoms. Examination of the penis revealed a condition similar to case No. I., with the exception that there was present in this patient an organic stricture. He was submitted for operation, and the stricture was cured; but as his other trouble still continued, I advised the treatment with the rectal psychrophore, together with the same strict hygienic course of treatment as in Case I. This was strictly followed out and the result was a good one. The course of treatment in this case extended over a period of eight weeks, and sexual intercourse was interdicted for six weeks longer. It is now eighteen months since he ceased all treatment, and there has been no return of the old trouble.

Case III.—S. H——, aged thirty-two years, married six months. Extremely nervous and irritable man. Complains that it is impossible for him to approach his wife without having an erection, which is extremely painful and which is almost immediately attended with a premature ejaculation. The act of coition is with him an utter impossibility. Sexual thoughts, pictures of nude persons, etc., all help to produce this abnormal erection and premature ejaculation. Patient feels himself a very miserable man, and thinks the time is not far distant when he will be entirely impotent. This latter idea is attributed to the fact that he has noticed a white glairy discharge from his penis, which occurs after urinating, but most frequently after a movement of the bowels. He considers this discharge to be semen, but on microscopic examination it was found to contain no spermatozoa, but to be of prostatic origin. Examination of penis reveals a condition similar to Case I. The treatment was the same as above, and a good result was established in seven weeks. It is now thirteen months since patient ceased treatment, and he writes that he is in perfect condition.

Appended here is the summary of the histories of a few more cases.

Case IV.—C. P——, aged thirty-three, unmarried; merchant. Complains of defective memory. Forced conceptions bother his mind constantly. Has led a very dissipated life. Does not like to be left alone, and at present feels very much discouraged and despondent over his condition. Frequent seminal emissions. Imperfect erections. Premature ejaculations and intromission impossible. Bowels constipated. Hyperæsthetic prostatic urethra. Treatment, laxative pill for bowels; Weir Mitchell's rest cure (modified); rectal psychrophore. After seven weeks' treatment perfect result.

Case V.—F. H. L.——, complains of lack of vigor. Feels that he does not do his work in a way which does justice to himself. Discouraged and despondent. Complains of frequent seminal emissions. Erections are fairly well developed, but the ejaculations are precipitate and do not give him the pleasure they formerly did. Patient is fairly well nourished and of a very active disposition. Examination of penis revealed an extremely hyperæsthetic prostatic urethra. Strict hygienic course of treatment with rectal psychrophore. Good result.

Case VI.—A. L——, aged thirty years; married. Very hard-working man and very much worried about himself. Has a double murmur. Complains of nightly pollutions. Is covered with an eruption due to the enormous amount of bromide that he has been taking. Marked dorsal and shoulder pains. Feels fatigued and weary the greater part of the day. An erection to him is a rarity. Emissions are attended with pain and severe palpitation. Stricture was found in this case and divided. Treatment: Modified rest cure, with rectal psychrophore. Very much improved after six weeks' treatment. Patient then went home and have not heard from him since.

Case VII.—N. F——, aged thirty. Five months ago patient began to notice a discharge from the urethra which gave him, as the patient explains it, a feeling similar to that which he experienced when he indulged in sexual intercourse. Sexual abuses had been carried on for years, until patient found that his erections were getting more and more imperfect, and that intromission was difficult. Memory poor, and he seems to have lost all energy to do any work. Sleeps well, but does not feel the benefit of the rest that he should. Pain in extreme lower portion of spine. Strict hygienic course of treatment, with rectal psychrophore. Result a very good one.

Case VIII.—L. A——, aged thirty-two, merchant; married six years. Extremely irritable and nervous man. Complains of inability to have proper sexual relations with his wife. Erections are very weak. Has no seminal emissions. Was accustomed to have sexual intercourse with his wife five and six times weekly during the first five years of his married life. Man appears poorly nourished and suffers considerable dorsal and shoulder pain. Extremely hyperæsthetic prostatic urethra and an organic stricture of small calibre, which was overcome by sound treatment. As the other symptoms were still present to a slight degree I advised rectal psycrophore, and after three weeks patient was discharged as well.

Case IX.—J. S——, aged twenty-four; unmarried. Addicted to masturbation. Complains of frequent seminal emissions. Pain over dorsal portion of spine. Inability to concentrate his mind upon his work. Has noticed some deposits in his urine, and supposed it to be semen. Over this he has worried very much. Erections are very feeble. Ejaculations are premature. Penis is cold and flabby. Patient himself is a pale, anæmic, and ill-nourished looking individual. Has had gonorrhœa twice. No stricture. Hyperæsthetic prostatic urethra. Strict hygienic course of treatment, with rectal psychrophore.

Case X.—J. J——, aged twenty-three; insurance agent. Denied masturbation, but admits having indulged in sexual intercourse to excess. His erections have been growing more and more feeble. His desire is almost abolished and no pleasure is derived from the ejaculation. He complains also of an inability to retain his urine for any great length of time. He fre-

quently suffers pain after its passage. No stricture, but an extremely hyperæsthetic prostatic portion of the urethra was found. Strict hygienic course of treatment, together with the rectal psychrophore, was followed out. Good result after five weeks' treatment.

Case XI.—L. A——, aged twenty-four, clerk; unmarried. Addicted to masturbation and sexual dissipation. Complains of frequent seminal emissions, premature ejaculation, and inability to have intromission. Insomnia is a constant symptom with this man. Hyperæsthetic prostatic urethra. Treatment same as above. Result a good one.

Case XII.—J. K——, aged twenty-six; law student. Pale, anæmic-looking individual. Complains of seminal emissions, which he thinks were brought on by excessive masturbation. Is unable to concentrate his mind upon his work. Sleeps poorly. Has dorsal pain more or less constant all day long. Lately has observed that his erections have been growing weaker, and that intromission is difficult. Denies ever having had any venereal trouble. No stricture. Hyperæsthetic prostatic urethra. Treatment same as above. Good result.

Thus I might go on adding to this list, but I consider the above cases a sufficient number to give the reader an idea of what class of patients can be benefited by this method of treatment, and what is to be expected.

Now, it may be said, firstly, that just as much success in treatment can be obtained by the intelligent use of sounds and the urethral psychophore. I do not deny this, but I must say that in my own experience I have not met with such rapid improvement as when the rectal method was employed. Secondly, the use of the above instruments in the hands of inexperienced practitioners is not to be recommended. Thirdly, how often do we find the external meatus of the penis too small to admit the passage of a sound of proper size. Then an operation, which is always disagreeable for the patient, must be resorted to, in order to correct the obstacle. Why should we not, therefore, if we can, avoid all these little difficulties, and make use of the more simple and encouraging method of treatment?

113 West Seventy-seventh Street.

Progress of Medical Science.

Thermodine.—Dr. Schmitt describes this substance as occurring in white pointed crystals, without odor and almost tasteless, although upon trituration there is developed a special aromatic odor, and after some seconds, if a fragment is placed upon the tongue, a persistent bitter taste is perceived. It is slightly soluble in cold (1 to 2,600), more easily in warm water (1 to 450), but readily in alcohol, ether, benzine, carbon disulphide, and chloroform. While physiological researches have demonstrated the harmlessness of doses, even relatively large, in healthy men, they have also determined its method of elimination. It is absorbed with the aid of the lactic acid of the stomach, is decomposed slowly in the economy into amidophenol, which is eliminated in the urine, probably also in the perspiration, and possibly in the saliva. A small proportion, if the dose is large, may be eliminated unchanged. The dose employed at which anti-thermic effects have been manifest is between six and seven grains. On twenty-nine patients, suffering from typhoid fever, influenza, tuberculosis, articular rheumatism, and pneumonia, the effect was found to be a gradual fall of temperature, commencing generally within an hour after its administration; this fall is gradual, reaching its lowest point within about two hours. This point is retained up to the third or fourth hour, when the ascent takes place in the same regular and slow manner as the fall, and the initial degree is reached generally in from seven to nine hours after the administration of the drug. The extent of the fall of temperature depends somewhat upon the dose. Five grains in tuberculosis does not always give appreciable results; eight grains are usually sufficient. Tuberculosis is more easily influenced and with smaller doses than is typhoid fever, and pneumonic fever is less amenable to this drug. The pulse curve follows closely that of the temperature, although the pulse may be influenced later than the temperature as regards the diminution of the number of beats, but it is likely to become accelerated as soon as the temperature commences to rise. Sometimes the pulse-rate remains unchanged although there is a notable lowering of temperature. There have been no accidents in the use of this drug which are worthy of record; no gastric disturbances, vomiting, cyanosis, nor collapse. Occasionally sweating, and more rarely chilly sensations, have been noted. The drug apparently does not modify the hæmoglobin. The remedy has been generally administered in the morning in a single dose, and the quantity has been from the amount above named up to (rarely) fifteen grains. In conclusion, it can be said that thermodine is an antipyretic without danger, constant in its action, but very slow in producing this effect, and its results are sufficiently prolonged. It presents certain advantages over phenacetine, although it is inferior to it in activity, and it is expensive.—*The American Journal of the Medical Sciences.*

Typhoid Septicæmia and Pseudo-typhoid Infection.—Cases occur which in their course and chief symptoms closely resemble typhoid, but which on minute pathological examination show an absence not only of the ordinary typhoid characteristics, but also of any other signs which could lead to a certain diagnosis as to the nature of the affection. Dr. Banti describes some cases of this nature, of which the following notes will give the chief characteristics (*The British Medical Journal*). The first case was exposed to typhoid infection, and shortly afterward she became ill with headache, loss of appetite, and afterward fever. She had a typical typhoid facies, with dry tongue, slight delirium, subsultus tendinum, etc., but all through the course of the affection there was a complete absence of diarrhœa, cutaneous rash, meteorism, and enlargement of the spleen. The case terminated fatally after the third week. The post-mortem examination showed a complete absence of enlarged follicles in the intestines, a single minute ulcer in the end of the duodenum, a small spleen, a normal liver and mesenteric glands. The kidneys were slightly enlarged, and showed cloudy swelling of their epithelium. The blood and juices of the organs yielded typical cultures of the typhoid bacillus. The reason for the absence of the usual pathological signs of typhoid in the above case is difficult to find, but the author suggests that perhaps the body became infected through the small ulcer found in the jejunum, giving the infection a septicæmic character, and preventing the usual lesion of the intestinal lymphatic apparatus. The cases of pseudo-typhoid described in the same paper all occurred in one household, the members of which were affected one after the other with an affection clinically almost impossible to distinguish from true typhoid. The only symptom failing was the usual petechial rash. One case ended fatally, and on examination showed a complete absence of bacilli from the blood or exudations. The spleen was much enlarged, also the intestinal solitary glands. Typical typhoid ulceration was wanting, but there was an extensive intense enteritis. This group of cases would be extremely difficult, if not impossible, during life to differentiate from cases of true typhoid, unless one insists on the presence of a rash as a sign of this disease; yet the pathological examination excluded the possibility of considering them as such. The author prefers to group them under the heading "pseudo-typhoid."

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, April 13, 1895.

TREATMENT OF AFFECTIONS OF THE HEART FOLLOWING INFLUENZA.

DR. ERNEST SANSOM gives an account in *The Practitioner* of the nervous disturbances of the heart following influenza, and adds some practical points in treatment. For influenza itself, Dr. Sansom seems to rely chiefly on sulpho-carbolate of soda in half-drachm doses —for what reason he does not tell. He adds to this, however, when needed, quinine and phenacetin for fever, and, in adynamia, five grains of musk.

The signs and symptoms referred to the heart resulting from influenza in cases under the writer's observation were thus distributed: In one hundred cases: pain referred to the heart, twenty-three cases; the rapid heart (tachycardia), thirty-seven cases; the irregular heart (arhythmia cordis), twenty-five cases; the slow heart (bradycardia), five cases; organic disease of the heart, ten cases.

In heart pain he gives a hypodermic of morphia with a diffusable stimulant such as: Spiritus ætheris, 3 ss.; spiritus ammoniæ co., 3 ss.; tinct. sumbul, 3 ss.; aquæ camphoræ, ℥ iss.; to be taken as a draught before the administration of morphia, and repeated an hour afterward. Once the severity of the pain is thus mitigated, other agents than morphia should be employed. Quinine in five-grain doses dissolved in hydrobromic acid is often very effectual. Local sedative and counter-irritant applications may also be required.

Tachycardia after influenza is sometimes not noticed and the pulse may not be much above 100. Some of the vaso-motor and eye symptoms of Graves's disease may be present. Dr. Sansom regards digitalis and strophanthus as not only useless but dangerous, and he also avoids opium. He prescribes bromides with arsenic and symptomatic drugs for dyspeptic symptoms which are apt to be present. In many cases drugs are of no avail, and he advises that a mild galvanic current be given three times a day for six months! He states truly that patience is required. The irregular heart is usually associated with symptoms like those with tachycardia, and much the same treatment is indicated.

Bradycardia sometimes occurs and may be severe and persistent. In one case the pulse fell to 19 per minute. Phenacetin and camphor with local warmth and counter-irritation are effective in mild cases. In the more obstinate tincture of belladonna may be given in ten-drop doses.

HYPNOTISM AND CRIME.

THE newspapers announce that the Supreme Court of Kansas has rendered a decision in which hypnotism is recognized, both as a defence and as a ground for conviction of crime. The case passed on came up from the County District Court. Thomas McDonald, without apparent provocation, shot and killed Thomas Patton near his home, in Winfield, May 5, 1894. He was arrested, charged with murder, and set up a defence that he was under the hypnotic influence of Anderson Gray, and was neither legally nor morally responsible for the deed. He was acquitted, and then Gray was put under arrest and tried for the murder. He was found guilty of murder in the first degree, notwithstanding the fact that he was not present when the crime was committed, the evidence for the State only going to show that he caused McDonald to commit the murder through hypnotic influence. An appeal was taken to the Supreme Court, and, in an opinion rendered, the ruling of the lower court was sustained.

If the above represents the truth about the case we should feel that the decision was entirely premature and unwarranted by our present knowledge of hypnotism. There are several problems which would have to be solved before an intelligent court could render the decision which it did. First, it would have to define hypnotism and its degrees; next, it would have to furnish some indisputable evidence that a particular individual was hypnotized, and finally, it would have to show that a person otherwise not criminally disposed could be made to do a murderous act while in this hypnotic state. To us it seems practically impossible that a court of laymen could solve these problems, and as a matter of fact we believe that the element of hypnotism played a very small part in the determination of the judicial opinion. It was rather a case of very undue influence exercised by a person of strong character upon one who was intellectually and morally weak.

CASTING UNJUST REFLECTIONS ON THE PHYSICIAN AS A PUBLIC OFFICER.

WE are credibly informed that a number of physicians of this city are urging his honor, the Mayor, to make up a new Board of Commissioners of Charities and Correction without including a Doctor of Medicine. This announcement will amaze the medical profession of New York, for it has been generally assumed, of late years, that it is essential that at least one of the three members of this important commission should be a physician. Certainly this is true, when we consider that they have the management of Bellevue Hospital, as well as the great medical institutions on Blackwell's Island. It seems impossible to conceive of any thoroughly good management without the presence of an expert in medicine and surgery on the Board. In certain emergencies the laymen appointed will be obliged to consult a physician in order to have a proper comprehension of their duties. We all know the results that follow when laymen have the undivided control of medical affairs. They either put their feet upon the necks of the doctors, which is said to have been the policy of a great hospital in this city,

some years ago, or they have a few favored ones in the medical profession whose will and wishes are law to them. The results of such a system are not beneficial to the matters in hand. We can scarcely imagine a proper motive for this attempt by members of our profession to foul their nest. Truly, "a man's foes are those of his own household." Is it possible that any of the professors in the undergraduate colleges are so anxious to secure the undivided and uninspected control of the Bellevue and Charity Hospitals, for the benefit of their institutions, that they are desirous of preventing the appointment of an independent member of the medical profession? We can hardly assume this to be the case, but since we know the origin of the opposition to a physician on this Board, we are obliged to suspect it. Unless the medical profession repects itself, it can never be respected by the community at large. To acknowledge that a doctor is not fit to be on the Board of Commissioners of Charities and Correction is to cast a reflection on our own class which we are sorry that any member of the profession should appear to be willing to do. We trust the Mayor will not listen to any advisers who do not recommend the appointment of a physician of high character and executive ability to a Board where such a man can better serve the city than a member of any other class.

PICTURES OF THE COUNTRY PRACTITIONER.

The very pleasant fashion of publishing the pictures of eminent medical men in medical journals has become a feature of the day, and is particularly developed in the West. We rarely open one of our esteemed contemporaries now without finding a picture of some rising or risen light. The practice is one that has many things to commend it; for one often appreciates at a truer value the writings of a man whose face is known. An article that seems vigorous, original, and striking may receive a more cautious interpretation after seeing the counterfeit presentment of its author.

We are particularly pleased to see that the *Cincinnati Medical Journal* is taking up the cause of the country practitioner, and has begun a series of illustrations of the representative men of this class in Illinois. We hear a great deal and say a great deal about the country practitioner—his hardships, his struggles, his resourcefulness, his utility, and his success as a factor in society. Our contemporary gives us pictures of twenty-nine of the class, and promises more. He begins with Illinois, because "in no State has the medical profession played a more important part," or, apparently, held more offices—though in this latter point injustice is perhaps done to Ohio.

The faces of the Illinois practitioners show them to be a vigorous and healthy-looking set of men. There are no sunken eyes or hollow cheeks, and, unlike the Bostonians, none of them are bald. We note that the tendency to wear a patriarchal beard is dying out. Altogether, the collection is flattering to the personal qualities of Illinois doctors, and we await with some eagerness to see if other States can do as well.

SHORT-HAND IN MEDICINE.

There is so much to be learned by the medical student that the addition of short-hand seems rather unnecessary. It is a fascinating art and, no doubt, can be made of considerable service to professional men. But it requires much time to learn it, and it is of no use unless well learned. The time might, in most cases, be better spent. Still, in London short-hand seems to be popular, and a prosperous Society of Medical Phonographers, numbering over one hundred, exists. The Society publishes a monthly journal, and it has, we are told, led to the discovery that many physicians, who were never suspected of the accomplishment, were at one time quite skilful with the hooks and lines.

News of the Week.

The Arkansas Medical Law.—A bill was recently introduced into the Arkansas Legislature, repealing the present medical law, and creating county instead of State boards of medical examiners. The Governor vetoed the bill, but the House promptly passed it again over his veto by a vote of 51 to 33.

Unfavorable Report on Antitoxin.—After a thorough study in various hospitals of Berlin of the use of Behring's diphtheria-serum, Passed Assistant Surgeon F. J. B. Cordeiro, U. S. N., in a report to the Surgeon-General of the Navy, concludes that so far proof is lacking of the value of antitoxin in the treatment of diphtheria. Dr. Cordeiro adopts the following opinions of Kassowitz: "1. A large number of children treated with both small and large immunizing doses have within a few weeks acquired diphtheria, and some of them have died of it. We do not possess a single scientific proof that a case of diphtheria was ever prevented by the immunizing process. 2. Children who during a first sickness have been treated with large doses of serum have a short time after acquired diphtheria anew. They were not rendered immune either by their sickness or the largest doses of the antitoxin. 3. In a large number of cases children have been treated on the first or second day of their illness with the fullest doses of the antitoxin and have died. 4. It is certain that a large part of those who have died notwithstanding the serum treatment did not die from the effects of a mixed infection, but directly from the specific effects of the Löffler bacillus. 5. Heart and other post-diphtheritic paralyses are also seen in early and fully treated cases, and they occur as often as they did before the serum treatment. 6. Of a fever fall by crisis in the first twenty-four hours, and of a pronounced antipyretic effect of the serum, most observers have seen nothing or next to nothing. 7. The separation of the membranes follows in the cases that run a favorable course in the customary manner. But often there is an extension of the local process, and a renewal of the already separated membranes during and after the serum treatment.

"The burden of proof lies with Behring and his coworkers. The world will eagerly and only too willingly receive this proof. We know that the former ex-

travagant promises are out of the question, but we should be grateful to have it demonstrated that the serum can reduce the mortality by even one per cent. As yet we have not the slightest basis on which to found an expectation that fewer children will die in the future of this disease on account of the serum treatment."

Dr. Cordeiro's paper will be published in full in the next annual report of the Surgeon-General of the Navy.

The Cholera is beginning to increase again in Russia with the advent of milder weather. Between March 10th and March 23d, in the province of Podolia, there were eleven cases of cholera and six deaths from that disease. From March 10th to March 16th there were fifty-six cases of cholera and four deaths in the province of Volhynia.

Cardiocentesis.—In our editorial article on this subject (March 30th) the statistics collected from the Index Catalogue should have been credited to Dr. James R. Church, of Washington, D. C. (*Medical News*, October 27, 1894), instead of Dr. Allen Thomson Sloan, as implied.

A Novel and Popular Plan.—The Cleveland Medical Society has adopted the novel plan of having addresses made and clinics held before the Society once every three months by men of prominence throughout the country. The secretary reports that he receives requests from all parts of the United States from the leading men in the profession for opportunity to read papers before the Society. At the last quarterly meeting, Dr. M. Allen Starr, of this city, read a paper on the "Mechanism and Causation of Nervous Diseases."

Legalized Dissection in New Jersey.—An act to provide for the incorporation of pathological and anatomical associations for the advancement of medical and surgical science, and the legalization of dissection of paupers, has been passed by the Legislature of New Jersey, and has been duly signed by the Governor.

A Well-deserved Compliment.—Dr. I. Boas, of Berlin, has been elected President of the Society of Post-graduate Medical Instruction of Berlin. This is a well-deserved compliment to a gentleman whose reputation in his specialty is world-wide.

The Late Dr. Alfred L. Loomis.—At a stated meeting of the New York Academy of Medicine, held on Thursday evening, April 4, 1895, the following resolutions were passed :

Whereas, Our associate and former President, Alfred L. Loomis, M.D., LL.D., has been removed from among us by death, therefore be it

Resolved, That in the death of this distinguished man the profession of medicine has lost one of its ablest teachers, one of its wisest leaders, and that the Academy of Medicine has lost a Fellow who contributed largely to its present prosperity; for, at a time when it had become important that a new site should be secured, it was greatly through the courage and enterprise of Dr. Loomis that this was accomplished and the present large and sufficient building erected.

Resolved, That in view of the position occupied by Dr. Loomis in relation to this Academy, it is recommended that a memorial meeting be held in the hall of the Academy on the first Thursday in May, and that the President be requested to invite representative speakers and take such further action as he may deem appropriate.

Resolved, That a copy of these resolutions be sent to the family of Dr. Loomis, and that they be published in the secular and medical press.

William M. Polk, Chairman,
Francis Delafield,
Andrew H. Smith,
Committee.

Georgia Physicians Practising Illegally.—A report comes from Macon, Ga., that the discovery has been made that a very large proportion of the profession throughout the State are practising illegally and are guilty of a misdemeanor. Under an act passed by the last Legislature, all physicians were required to register by January 1st in the Court of Ordinary of their respective counties. More than half of the physicians of the State, it is said, have neglected to do this.

Omaha Medical College.—The Omaha Medical College graduated a class of twenty-four, April 4th. The address was delivered by Chancellor W. S. Chaplin, of Washington University, St. Louis, on "Medical Education; what it was, is, and ought to be."

Bovine Tuberculosis.—The Governor of New Hampshire has vetoed the bill recently passed by the Legislature of that State appropriating $100,000 for the suppression of bovine tuberculosis. Farmers' vote!

A Tax on Physicians.—The *North Carolina Medical Journal* writes editorially, in sharp language, concerning a recent bill in the State Legislature levying a tax of $10 a year on every practising physician. Such legislation is unprecedented, and seems to have absolutely no reasonable foundation.

Medical Practice in Kansas.—A bill this year to regulate the practice of medicine in Kansas met with the following result : It passed the House but was defeated in the Senate. One of the legislators said on the floor :

"We Western people can get a lot of old women who are better than any of them."

Is this ignorance or is it politics?

Physicians' Fees in Illinois.—In the Illinois Legislature a bill was introduced regulating the fees of physicians and surgeons and providing for a maximum surgical fee of $100.

Reduction in the Fee for Life Insurance Examinations.—A very polite notice has been issued by one of the prominent metropolitan life insurance companies of this country to its examiners, to the effect that the fees for examination have been reduced from five to three dollars, and very naturally many of the examiners object to this. (*Maryland Medical Journal.*) Whether such a reduction is caused by the general depression of business, by a desire on the part of the company to make a better showing in expenses, or whether the great reduction in prices brought about by the Wilson bill and other causes has at last hit the physician, it is hard to say. At any rate any reduction is naturally met with much opposition, and Dr. DeLancey Rochester, of Buffalo, makes a very strong and dignified reply

to this cut-rate order in the *New York Medical Journal*. He very clearly shows that a careful examination is worth at the very least five dollars, and in private practice usually more is charged, and yet here is a large company that is inviting its physicians to make a less careful examination, for it is very evident that an examination for five dollars is one thing, and one for three another, and if a company reduces its fees to three dollars, the physician who still continues to do the work gives a three-dollar examination.

The American Academy of Medicine.—The twentieth annual meeting of the American Academy of Medicine will be held in one of the buildings of the Johns Hopkins University, Baltimore, on Saturday, May 4th, and on Monday, May 6, 1895. The "Headquarters" of the Fellows of the Academy and the meetings of the Council will be at the "Stafford." The meeting will open at ten o'clock on Saturday morning with an executive session of the Fellows of the Academy exclusively; the reading of the papers will begin at about eleven. The morning session will close at one o'clock, and the session of Saturday afternoon will extend from three to six. The "Reunion Session" will be held on Saturday evening. By a standing rule the price of the tickets for the supper is fixed at two dollars. Attendance at the reunion session is not confined to the Fellows exclusively, hence any member may bring friends with him by arranging for their tickets with the committee. For the past two years ladies have been present at this session and have added to the enjoyment. This session of Monday will begin with a short executive meeting, after which the reading of papers will be resumed; after a recess at one, the afternoon session will begin at three and continue until adjournment. Members of the profession, and others who may be interested in the topics treated by the papers, are cordially invited to attend the open sessions of the Academy.

The Wooten Bill to regulate the practice of medicine and to prescribe the qualifications of physicians and surgeons, now before the Texas Legislature, has been reported back by the Committee on Public Health with the recommendation that it do pass, as amended by the committee. It repeals all acts in conflict with it, of course.

The College Commencements.—The Fort Wayne College of Medicine held its annual commencement on March 12th.

The Beaumont Hospital Medical College held its annual commencement exercises Thursday evening, March 14th, at which seventeen graduates were granted the degree of M.D.

The Barnes Medical College held its third annual commencement March 14th, graduating a class of sixty-four.

The Missouri Medical College graduated a class of seventy on March 19th.

The Marion-Sims College of Medicine held its annual graduating exercises on March 18th, conferring degrees on a class of fifty-four. Dr. J. M. Mathews, of Louisville, addressed the graduates of the Marion-Sims College on the evening of March 18th.

The University of Louisville held its commencement on March 18th.

Massachusetts has also gone into the drug business, and its Board of Health has arranged to supply diphtheria antitoxin.

The St. Louis Public Library undertook to care for the medical libraries of several of the local societies. According to the *Medical Review* the pledge has not been kept. Books are not catalogued, pamphlets not bound, and, most shocking of all, the library does not subscribe for the leading medical weekly of this country, the MEDICAL RECORD. We agree with the *Review* that the laggard should be stirred up or the books restored.

The Buffalo General Hospital has received the munificent gift of $55,000, which is to be applied to the building of a new structure. This royal donation was made by four of Buffalo's most philanthropic women. Mrs. George B. Gates contributed $40,000 of the amount, and her three daughters—namely, Mrs. William Hamlin, Mrs. Charles W. Pardee, and Miss Elizabeth Gates—each added $5,000 to the sum.

Life Insurance Companies depend for their success upon the skill, intelligence, and character of the medical men who examine for them. It behooves them to treat the medical profession in a generous manner. Yet the New York Life has just reduced its fee for examinations to three dollars, and the Equitable, and we presume other companies, send out circulars begging for free information regarding the character of those whom they employ.

National Association of Railway Surgeons.—The Annual Convention of the National Association of Railway Surgeons will be held at Chicago, on May 1, 2, and 3, 1895. This date was selected by the officers and members of the executive committee, so that members wishing to attend the meeting of the American Medical Association, which is to be held on May 7th and following days, will be able to do so on the same trip.

Florida Medical Association.—The seventy-second annual meeting of this Association will be held at Gainesville on Tuesday and Wednesday, April 16 and 17, 1895. The president of the society is Dr. J. D. Rush, of Apalachicola, and the secretary, Dr. J. D. Fernandez, of Jacksonville.

Dental Law in Nebraska.—The dentists of Nebraska have now a law, just enacted, by which the present State Board of Health is made judge of their fitness for practice. The law is a copy of the medical practice act, but made to apply to dentists.

The Code Controversy will not down, and the American Medical Association will doubtless be obliged to modify its position in regard to it to meet this change in views, which is rapidly growing, and which will result, if it goes on, in the disintegration and final annihilation of this august body.

The Cleveland Medical Society and the Mississippi Valley Medical Association have recently joined the Medical Society of the State of New York in its onslaught upon the Code, and the combination must have a powerful influence in bringing the National body to its senses.—*New York Medical Times.*

Reviews and Notices.

An International System of Electro-therapeutics for Students, General Practitioners, and Specialists. By Horatio R. Bigelow, M.D., Permanent Member of the American Medical Association, etc., and Thirty-eight Associate Editors. Thoroughly illustrated. Philadelphia: The F. A. Davis Co. 1894.

A subject treated by thirty-nine different persons acquainted with its nature and the laws that govern it is deserving of respect and careful consideration. Goelet, Sajous, Rockwell, Riggs, Morton, Prince, Mary Putnam-Jacobi, Frederick Peterson, W. J. Morton, A. Wilmer Duff, and Wesley Mills are the names of some of the associates that are especially attractive. The chapters on electro-physics, animal electricity, static electricity, and magnetism are of general interest, together with those concerning currents and apparatus, and electro-physiology. Apostoli's methods are considered at length, as is also the use of electricity in diseases of the nose, naso-pharynx, pharynx, and larynx. Papers on facial blemishes, diseases of the skin, the eye, the intestinal tract, the nervous system, etc., capable of improvement or cure by electricity, are carefully written by well-known specialists and general practitioners. Every effort has been made to place electro-therapeutics on a firm basis, by securing from competent physicians a record of their experience and observation. The result is a useful compendium of medical facts relating to the cure or alleviation of disease by electricity, and is certain to meet the requirements of the ordinary student, specialist, and general practitioner.

Healthful Womanhood and Childhood. Plain Talks to non-Professional Readers Relative to Healthy and Diseased Conditions Peculiar to Women, and Concerning the Care of Young Children. By Henry Bixby Hemenway, A.M., M.D., Instructor in Laryngology and Diseases of the Chest, Rush Medical College, Chicago. Evanston: V. T. Hemenway & Co. 1894.

This book is without a reason for being. It says too much and too little. It is not medical literature, and it is not literary writing. In it women of the day are arraigned because of their wide dissemblance to the classic statues of antiquity, and feminine imperfections generally are laid to corsets and high heels. "Many cases of nervous disorder, even of imperfect vision, have been traced to high heels." Diseased conditions are not appropriate subjects for plain talks to non-professional readers. For this and other reasons, the Hemenway's production is neither fish, flesh, fowl, nor good red herring. It is worthless reading and waste of time.

A Pathogenetic Materia Medica: Based on Drs. Hughes's and Dake's Cyclopædia of Drug Pathogenesy. By the Medical Investigation Club of Baltimore, Md. Members, Honorary: Elias C. Price, M.D., Professor Institutes and Hygiene, Southern Homœopathic Medical College. Active: Eldridge C. Price, M.D., Professor of Materia Medica and Therapeutics; Robert W. Mifflin, M.D., Professor of Pathology and Practice of Medicine; O. Edward Janney, M.D., Professor of Pædology and Orthopædic Surgery; George T. Shower, M.D., Associate Professor of Physiology and Lecturer on Pharmacy and Toxicology; Henry Chandlee, M.D., Professor of Obstetrics, Southern Homœopathic Medical College. Philadelphia: Boericke & Tafel. 1895.

The author club or the club author of this work has given here the result of several years' investigation of the materia medica, some of which has already appeared in periodical literature. It cannot be considered at all complete, since but forty-seven drugs have been proved. It will, however, be found of value as a repertory of important and well-proved drugs, used in connection with other works. Some of the symptomatologies are far from being full. The work shows the need of a thorough and scientific retesting of even the best-known drugs, and indicates the character which future materia medica investigations and efforts at systematizing must take on.

Relations of Diseases of the Eye to General Diseases. By Max Knies, M.D., Professor Extraordinary at the University of Freiberg. Forming a supplementary volume to every Manual and Text-book of Practical Medicine and Ophthalmology. Edited by Henry D. Noyes, M.D., Professor of Ophthalmology, Bellevue Medical College; Executive Surgeon to the New York Eye and Ear Infirmary, etc. Pp. 467. New York: William Wood & Company. 1895.

The book is of convenient size and the text is printed in large, clear type. There are about thirty illustrations placed in the body of the text. The modest prefaces of author and editor portend directness and lack of verbosity in the treatment of the subject which the text fully substantiates. The subject-matter is divided into nine chapters, of which the first is devoted to the nervous system. This chapter comprises 245 pages. In it is found an excellent discussion of the anatomical relations of the eye to the brain, which is up to date and is of much value to the ophthalmologist and neurologist. A careful consideration of the various affections of the eye and of its appendages which occur as a result of diseases of the nervous system follows. The second chapter is devoted to a discussion of the relation of diseases of the eye to diseases of the skin. The subject is treated in a very clear, concise, and comprehensive manner. Chapters on the relation of diseases of the eye to diseases of the respiratory, circulatory, urinary, and sexual organs follow. The effects of poisons and of the infectious diseases are treated of in the same chapter. This, we think, is a very happy combination, serving as it does to acknowledge the similarity of the effects of poisons and of the ptomaines, generated by the etiological factors of infectious diseases on the system. The ninth chapter is devoted to a consideration of the relation of the eye to the non-infectious, constitutional diseases, which includes anæmia, plethora, obesity, Addison's disease, chlorosis, diabetes, etc. This chapter is fully up to the excellent standard of those which precede it.

The discussion of the disorders of the voluntary muscles, accompanying disease in other parts of the body, makes no mention of the so-called "insufficiencies," an omission which does not detract in any way from the value of the work.

A careful perusal of the contents of this volume convinces us that it is a work of high merit and of great practical value to those for whom it is intended. The author is to be congratulated on the production of a volume which treats so ably of a subject that is of such importance to so large a portion of the medical profession. Nothing farther need be said in commendation of the work performed by the editor of the American edition than to refer to his name.

Memoranda and Tables of Human Anatomy. Vol. I. By Justin Herold, A.M., M.D., formerly House Physician and Surgeon at St. Vincent's Hospital, New York, and Sebastian J. Wimmer, M.A., M.D. With Preface by Professor James E. Garretson, A.M., M.D. 18mo, pp. 296. Philadelphia: Medical Publishing Co. 1894.

This little work contains a well-arranged tabulated account of the origin and insertion of the muscles, and will doubtless be especially useful in preparing for examinations.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL SURGERY.

Stated Meeting, March 11, 1895.

B. Farquhar Curtis, M.D., Chairman.

Excision of the Tongue for Epithelioma.—Dr. C. N. Dowd presented two patients as examples of the cure of epithelioma of the tongue by operation. One case was in a man, operated upon by Dr. Hartley, through whose courtesy he presented the patient; the other was in a woman, operated upon by himself a year later, or three years and a quarter ago; in both the epithelioma involved the posterior portion of only one-half of the tongue, was of a diameter of about three-fourths of an inch, and in both one-half of the tongue was amputated by the Whitehead method; but in the case of the woman the tip of the tongue was saved. The woman was able to talk nearly as well since the operation as previously, and the man could also talk well. A quotation was read from Treves's "Manual of Operative Surgery," to the effect that it was very unwise to leave half of the tongue, as it became distorted and rolled about aimlessly. Dr. Dowd thought the present cases disproved that assertion. They also taught the lesson that one should operate early if he would give the patient the best chance for permanent cure. In a case operated upon last fall there had been recurrence in the glands of the neck, and he thought it safer always to remove these.

Dr. R. A. Sands said that his father, the late Dr. H. B. Sands, had done many operations for malignant disease of the tongue, and, so far as he knew, none of the cases in which he performed Whitehead's operation were now living, although he was an ardent advocate of that method when it first came out. Only one patient had lived over ten years. The speaker thought we should wait longer than two or three years before pronouncing definitely upon the cure.

Nephrectomy for Rupture of the Kidney.—Dr. F. Kammerer presented a specimen of ruptured kidney and the patient from whom it was removed. A girl of about eleven years had come under his observation four months ago with a history of having fallen two weeks before a distance of one story. She was picked up unconscious, had sustained fracture of the lower jaw, and, judging by the shock and severity of the symptoms, it appeared evident that there was some internal injury. She had passed some blood with the urine. When he first saw her she was in very feeble condition, the temperature ranged from 103° to 105° F., and at a second examination the following day a tumor was recognized in the left inguinal region as large as a cocoanut. The diagnosis was injury to the kidney; lumbar incision was made; a perinephritic cavity was reached from which some urine escaped; the kidney was found completely severed in a transverse direction, the lower quarter having receded from the upper three-quarters a distance of over an inch. The rupture had been as clean as a cut with a knife. Nothing was done except to tampon the wound, allow it to granulate, and urine to escape externally. The patient did well for six weeks, when there was rise of temperature, pointing to obstruction of drainage. An incision was made, the upper three-quarters of the kidney were found readily, the lower quarter had been replaced by a mass of cicatricial tissue, the normal tissue having been absorbed. This was not so astonishing when it was remembered that the lower portion had been severed from its connection with the renal vessels. He hesitated what to do, but inasmuch as the other kidney was sound, and believing that the inflammatory and suppurative process had extended into the remaining segment of the left kidney, and also knowing that fistulæ in the pelvis of the kidney were much more difficult to heal than those in the body of the organ, he decided to remove it. This was two months ago, and the patient had done well since.

Dr. Kammerer thought that usually in wounds of the kidney we should try to save the organ, but he could not agree with those who asserted that it must never be removed. If he should meet with a similar case to this one, he thought he would split the kidney in the median line, tampon the pelvis with the hope that the pelvis would close, and afterward secure union of the split portion. Possibly the kidney could be saved in that way.

Suture of the Musculo-spiral Nerve.—Dr. B. B. Gallaudet presented a man who had been brought to Bellevue Hospital, October, 1893, with a stab wound of the left arm, which had divided the musculo-spiral nerve and caused wrist-drop. The nerve was found by making an incision along the inner margin of the supinator longus, then tracing it to the divided end. The ends were about a fourth of an inch apart, held together by a piece of the sheath. He united them by fine silk, closed the wound, put the arm up in flexion. Improvement scarcely became perceptible before the end of the seventh month. After about a year there was full restoration of function. He impressed the importance of suturing divided nerves as soon as possible.

Dr. R. A. Sands had sutured the musculo-spiral twice, and had assisted at three other operations, all secondary, and it was noted that in all the restoration of function was delayed longer than one might have expected. In one in which his own persuasion had induced the patient to submit to an operation for the relief of wrist-drop following an injury by a scythe, he had given up hope of any benefit resulting, when, at the eighth month, improvement began and then progressed rapidly. Regarding the inner border of the supinator longus as a guide for finding the divided nerve, he said he had once assisted a well-known surgeon, who found himself much confused by the fact that at this point the supinator longus and brachialis anticus happened to be fused together, an anomaly which was not infrequent.

Dr. C. B. White mentioned a case in which sensation returned in from four to seven days, the divided nerve having been united not sooner than four months after the accident.

Dr. Lilienthal mentioned a case of interest, because of the difficulty in diagnosis, and the chairman, Dr. Curtis, said he believed the usual length of time before restoration of function after uniting the divided nerves was from six to nine months, although there had been exceptional cases where it had taken place much sooner. Sensation had been known to return within a few days, but there was always a question whether it had not been restored through other nerves going to the part, or whether it had been entirely lost.

A Report of Thirty-five Cases of Amputation of Omentum in Hernia Operations, with Exhibition of Patients and Specimens.—Dr. W. B. de Garmo first presented a number of men upon whom he had operated for hernia, and also portions of the omentum removed, and afterward read an abstract of a paper with the above title. In December, 1887, he had read a paper before the Academy of Medicine on the conservative treatment of irreducible and incarcerated hernia in which he had reported fifteen cases, in most of them reduction having been effected without operation. In consideration of the severity of the operation at that time, and the fact that the hernia returned as a rule, the plea for conservative treatment which he then made was proper, but since then there had been such advances that we must look upon the teachings of that paper as obsolete.

This evening he wished to report thirty-five cases of removal of omentum, in three of which omentum was removed from both sides, cases of double hernia. In none had there been death. In none had he had any anxiety

about the patient's life. Of the thirty-five cases nine were in females, of whom two had inguinal and seven femoral hernia. Of the twenty-six males twenty-four had inguinal, one femoral, one ventral hernia, three had omentum removed from both sides. Nine of the total number had incarceration with more or less inflammation of the omentum. It was thought desirable that the discussion should deal principally with the removal of omentum, and with this object in view no other cases had been mentioned. It seemed to the speaker that there was nothing more important in the whole field of surgical treatment of hernia, except possibly intestinal repair, than the methods which should be carried out in cases of this character. For twenty years protruding omentum had been his worst enemy in the mechanical treatment of hernia, and he was convinced that to it was also due a number of the deaths which had resulted from attempts at surgical cure. Experience had taught him that any operation which did not open up the canal to the internal ring was liable to fail because of the frequency of adherent omentum at the ring or within the abdomen. In several of his cases the hernia had been supposed to be perfectly reducible before the operation. In all the last twenty cases the canal had been opened to the internal ring. Having opened the canal, the hernial sac was freed from its adhesions and opened. As much omentum as would come down by gentle traction was brought out. If there were adhesions at the internal ring or within the abdomen they were broken up. At times it had been found necessary to extend the abdominal incision above the internal ring. The omentum was spread out on a sterilized towel and unfolded until it was a single layer and every vessel of size could be seen. Beginning at one edge of this fan-shaped piece of omentum, numerous ligatures were passed and tied, no one of which included a piece of fat larger than a lead-pencil. Every vessel which could be seen was tied without including any fatty tissue. The omentum was then cut away. There were seldom any bleeding points. Aristol was dusted upon the fresh edges. The stump was then allowed to drop back. Sometimes he had used as high as twenty ligatures. Many surgeons considered such care unnecessary, and continued to tie off with one or two ligatures, but Dr. de Garmo was convinced that it was due to just such a course that accidents had happened. Some of the advantages of using so many ligatures were that the knot could be cut closer, the stump spread out in the abdomen instead of forming a plug, which was liable to again extrude, the possibility of including intestine was avoided, etc.

Attention was directed to the necessity for freeing adhesions at the internal ring. He thought failure to do this in his early cases was the cause of pain when the patients got out of bed after the operation, the adhesions having been pulled upon on assuming the erect posture. Formerly he did not move the bowel, at present he did. Formerly he used No. 10 ligature, at present No. 8, because the larger size was less liable to cut through the delicate structures. Every precaution was taken against sepsis.

Until comparatively recently he had operated by Barker's method, later by Basini's, using kangaroo tendon posterior to the cord, silk-worm gut in the aponeurosis of the external oblique, buried. Of the twenty cases treated by the latter method (Basini's), none had relapsed. The patients usually wore a light bandage for a time.

Conclusions: 1. All irreducible hernias should be operated upon unless contra-indicated by the age or condition of the patient. 2. All omentum found outside of the abdomen, or which protruded under gentle traction, should be removed. 3. Multiple independent ligatures of good-sized silk; vessels ligated independently of any fat. 4. A film-forming substance of some kind was believed to protect in a measure from subsequent adhesions.

Dr. C. B. White said that in a good many of the cases under consideration the hernia was strangulated, and in that event he thought it would not be advisable to consume much time in ligating the omentum in the manner described in the paper. After freeing and tying the omentum he would draw it up into the abdomen out of the way by a catgut suture, passing the suture out and burying it in the external wound. The catgut would be absorbed and cause no trouble. He preferred silk suture in closing the wound.

Dr. Milliken thought one could recognize the presence of omentum before operation by its slightly nodular character, its peculiar consistency, etc. Silk-worm gut in the aponeurosis was unnecessary; kangaroo tendon would answer. He had abandoned the use of drainage. He was pleased to hear the author speak so favorably of Basini's operation.

Dr. Lilienthal disapproved of fastening the omentum with catgut as described by Dr. White, for, although catgut was used, adhesions would form quickly and hold it there.

The Chairman agreed with Dr. Lilienthal's remark. He thought a truss was useless after these operations; it could give no support until hernia had recurred.

Dr. de Garmo was convinced that it would be only a question of time before Dr. White would lose a patient if he continued to treat the omentum as he had stated. No structure of the body required to be handled more delicately than the omentum, and he had been surprised to witness the careless way in which good operators handled it. As to recognizing omentum in all cases by the feel, he showed some specimens which he thought would deceive anybody. He did not use drainage. He was himself somewhat doubtful as to the advantages of a truss or bandage except in fat patients.

Fibroma of the Brachial Plexus; Excision.—Dr. J. F. Erdman presented the specimen. It was from a man, forty-two years of age, who had first been operated upon in 1887 by Dr. Dana, who stretched the ulnar and median nerves for pain; later different surgeons had operated, amputating the forearm, then the arm, etc., the last operation prior to his having been done some months ago by Dr. Abbe, who took out a section of the posterior roots and divided the anterior roots of the cervical plexus. There had been only brief relief from pain after the operations by Dr. Abbe and Dr. Erdman. The brachial plexus removed showed fibrous nodules.

Intestinal Intussusception.—Dr. Erdman also presented a portion of the ileum, near the cæcum, which he had removed in a gangrenous condition in the case of a child which had suffered three days from obstruction. Anastomosis was made with Murphy's button. The child died five hours after operation.

SECTION ON GENERAL MEDICINE.

Stated Meeting, March 19, 1895.

William H. Porter, M.D., Chairman.

A Review of the Present State of our Knowledge of Gout, and a Discussion of its Comparative Frequency in America.—Louis Faugères Bishop, M.D., read the paper of the evening (see p. 454).

In discussing the subject, Dr. William H. Draper said that the subject had occupied his mind for a number of years. He thought the nervous theory of Cullom was incomplete, but it was important to consider it, for gout presented in many ways the symptoms of nervous diseases. Thus in its mode of attack the patient was awakened at night the same way as he was in a case of asthma, migraine, etc. The manifestations of gouty diathesis were of a nervous nature and suggested the existence of some peculiar condition of the nervous system that had something to do with the disease. Especially were these found in gouty females; one might suffer from migraine, another from acute inflammation,

etc. As to Sir Alfred Carrod's uric-acid theory he would like to say that it had been exaggerated as the essential cause. He knew from personal experience that persons might have much uric acid and not suffer from gout, and that others might have repeated attacks and not have deposits of urates. He would suggest that it was not an essential, and especially was this true of what was called irregular gout, particularly as it was found in women. The neuro-humoral theory was the natural outcome of the other theories. The individual could not be looked upon as a test-tube, and there was a tendency to exaggerate the work that was done in the chemical laboratory and to draw too largely conclusions from it. The vital forces must be taken into consideration.

A Gouty Habit.—That it was a constitutional vice was shown by its heredity, for it was just as hereditary as were form and feature. There was the curious fact that diabetes mellitus was said to be undoubtedly a gouty disease. Also that the diet which was good for the gouty patient was also good for the diabetic one.

Diet.—Dr. Draper had seen such benefit derived from animal food in cases of gout that he could not go behind the evidence, although he might not be in sympathy with all that had been claimed for this treatment. It seemed that the most likely explanation of this vice was the imperfect combustion of the carbohydrates and azotized foods. By this incomplete combustion nutrition was interfered with and compounds were formed that were not good for the system. Then, if the simple hypothesis that gout was a disease of suboxidation be true, it was evident that the dietetic question was important, for the oxygen must be sufficient for the supply of food. His experience had led him to believe that gouty patients did the best on azotized and starchy food, but they sometimes had little capacity for carbohydrates. Sometimes they had to forego the use of sweets, also fermented drinks, which sometimes caused gastric or nervous symptoms. He had seen persons who could not take starchy food, for when they did they suffered from showers of urates.

Dr. F. P. Kinnicutt said that he thought the neuro-humeral theory was the best of any that had been presented, and he also thought that there was more to be looked for than chemical causes. The neurotic symptoms were prominent, and often there was an exaltation of spirit preceding an attack of gout. He had employed piperazine and had found it quite useful. He had obtained good results from its use in cases of mild pyelitis in the presence of small calculi or irritation. There seemed no doubt that these cases in which he had used it were cases of myelitis, for they presented all the clinical signs. He therefore believed that piperazine had a distinct value in therapeutics. He remembered two children, of gouty parents, who had pyelitis, which yielded to this medicine. He believed that gout existed in America to-day to a very large extent, but perhaps more often in the irregular form than in the typical forms. He thought that it was not seen so very much in the hospitals, and so one might be led to think it was a disease that was not at all common, but it was very commonly found in private practice. He had found it most in women who were approaching the climacteric period.

Dr. Draper in a further discussion said that the paper referred to the action of the sodium alkalies upon the solubility of the biurates, and he thought it was of very great importance. Often when patients were sent to the springs they had severe attacks, and were told that it was bringing the urates out, but it was quite probable that it was only producing them. Good, pure water was the essential in the water-cure.

Dr. William H. Porter said he thought we had gone astray, especially as to the works of Sir William Roberts, and would have to come back to the neuro-humoral theory. Though the urates were present, yet there was something back of that. He believed that Dr. Roberts said that urates were not found in the blood, and that the urate of soda was made in the renal epithelial cells, which seemed to show that imperfect oxygenation was a cause. It seemed that the whole treatment resolved itself into dietetics and oxygenation.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 25, 1895.

Egbert H. Grandin, M.D., President, in the Chair.

Acute Localized vs. Diffuse Peritonitis in Women from a Clinical Stand-point, with Special Reference to the Question of Surgical Interference.—Dr. H. C. Coe, in some opening sentences in a paper bearing this title, questioned whether the enormous increase of medical literature did not sometimes act as a hindrance rather than a help to the practical application of the fundamental principles of medical science; whether it did not lead us to overlook more clearly defined points while seeking for those which were only possible. One result of the aggressive tendency of gynecology must strike every consultant, namely, the surgical education of the practitioner, so that in consultations it was often the latter rather than the former who suggested the advisability of operative interference. From one point of view this had produced good results, leading to the saving of life, but it had also led in many instances to fear where no fear should exist, and perhaps to interference where interference was unnecessary and proved disastrous. When we saw intelligent practitioners, when confronted with an ordinary case of pelvic suppuration, oppressed with the bugbear of impending rupture of a pyosalpinx, an accident which few specialists had seen; when we observed the apparently prevailing impression that the presence of tympanites associated with abdominal pain, rapid pulse, and elevation of the temperature necessitated the giving of a gloomy prognosis, we were led to ask whether we had improved very much upon our predecessors in practical knowledge of peritonitis. At any rate, there was still opportunity for profitable discussion.

He would pass by the characteristic symptoms presented by virulent general peritonitis, such, for example, as followed rupture of an ovarian or appendical abscess and terminated fatally in four or five days, for the question of differential diagnosis did not arise in such cases. It arose rather in those cases which ran their course in obscurity, and here a careful review of the history was all-important. Thus, the fact that the patient had had one or more previous attacks would lead to the suspicion of purely local trouble. The difficulty of distinguishihg between cases of tubal and appendical origin was well known, and even in supposed infection through the genital tract in puerperal cases a possible appendical origin must not be overlooked. But whatever might be the starting-point, it was important to establish the fact that at some time the pain and tenderness had been localized. The need of care in this regard was the greater because usually the question was obscured by narcotics. The duration of the symptoms for several days without becoming progressively worse pointed to the trouble being localized. The diagnosis became clearer in the presence of characteristic thermometric variations, sweating, etc., belonging to suppuration, but this might not be until late.

The common source of diagnostic errors in all abdominal affections was the attempt to base an opinion on any single symptom or group of symptoms which were supposed to be characteristic. Who had not observed, for instance, the classical "rapid, wiry pulse" of supposed diffuse peritonitis in the ordinary pelvic variety? Regarding the temperature, all must agree

with a modern writer that it furnished an unreliable guide, yet how often were we plunged into despair by a temperature of 104° or 105° F., and on the other hand were disposed to think all danger was over when it fell to 101° F. General abdominal pain and tenderness caused us anxiety, yet we might find its disappearance, on which we based a temporary hope, due only to an apathy which heralded death. Vomiting in a typical case of diffuse septic peritonitis was a characteristic symptom, but it was not always present until just before death, and, on the other hand, was frequently present in cases of localized peritonitis, especially when unwise feeding and medication kept the stomach in an irritable condition. Tympanites very properly caused us uneasiness, but it was no longer regarded as pathognomonic of general peritonitis, and was often excessive even in pelvic peritonitis. In the latter, it was less likely to be marked about the umbilicus or to be so persistent.

Referring to constipation, Dr. Coe said it was only after one had seen patients die of post-operative peritonitis on the seventh or eighth day after having had daily evacuations of the bowels, and others make a good recovery who did not respond to laxatives and enemata for five or six days, that he began to believe too much stress had been laid on this point. The blame lay with general surgeons.

When a persistent amelioration of all the unfavorable symptoms was noted after giving a laxative in a case in which the diagnosis between diffuse and localized peritonitis was doubtful, he had always felt justified in inferring that the latter condition was present, and in giving a favorable prognosis. If the improvement was only temporary, and there was a rapid return of the pain, vomiting, tympanites, and anxious facies, he had assumed that probably no amount of purgation would save the patient. And so with the application of cold and the administration of antipyretics, the response was more favorable in localized peritonitis and the less serious cases.

It was not, then, from the presence of any striking symptom or symptoms that one arrived at a decision in a doubtful case, but from the whole picture. To the experienced eye the look of a patient with fatal septic peritonitis was rarely misleading, yet it was not possible to describe it in words. The facies of a patient with localized peritonitis, no matter how severe the symptoms, was quite different from that of one in whom the inflammation had become general. The difference could be detected only by experience and close observation. A local examination might enable us to make the diagnosis of the pelvic origin of the trouble in some cases, but not in all, and we were compelled to judge by more general signs.

Dr. Coe referred to some experience with patients of a hysterical nature, and said it became obvious how important it was in private practice to recognize the harmless character of the condition before throwing a family into the deepest distress by hinting at the necessity of a formidable operation.

The question asked by the general practitioner, "Ought I to call in a surgeon, and if so, when?" could not be answered by hospital practice. In referring to abdominal section for acute general peritonitis, let it be understood that it was still a hospital operation—a desperate remedy for a desperate condition. In nearly all the successful cases the condition had been more or less localized, and it was in the localized condition that one found the legitimate field for operative interference. But even here it was seldom one felt justified, in private practice at least, in dealing in a radical manner with the tubal or pelvic disease during the hight of the localized peritonitis to which it had given rise. So long as one was reasonably sure that the process would not become general, he should put off operative measures until he could definitely locate a pus focus or felt sure that one existed. The vaginal route was a safe one for exploratory puncture or incision.

Peritonitis only a Symptom.—Dr. W. R. Pryor regarded peritonitis as only one of the symptoms of a certain process. This was proven by the fact that in some cases it was general and fatal, while in others it remained local because it had led to shutting off the real source of the trouble. Looking, then, at peritonitis as merely an exponent of some certain form of infection which had to be met, not by attacking the peritonitis, but by attacking the cause, we could devise some reasonable method of treatment. The difference between the effect of a diffuse peritonitis following the use of gauze packing and that following perforation of the appendix was due to the fact that in the former there was a mechanical or chemical irritation, while in the latter there was infection. Regarding the route of attack in peritonitis in which there was hope of removing the local cause, Dr. Pryor thought our improved methods and instruments should make it safe to do cœliotomy instead of working blindly in the vagina. He did not believe in a secondary operation for peritonitis following cœliotomy, for the reason that it only resulted in further depriving the patient of her vitality.

Dr. James P. Tuttle doubted very much whether we were in a position to go so far as to say that there was no such thing as idiopathic peritonitis; that peritonitis was always due to some such local condition as appendicitis, ovarian abscess, etc., and that therefore it was always a surgical disease. He related a case showing the danger of assuming that constipation and tympanites were necessarily due to the peritonitis, and on that assumption giving enemata and purgatives. In the case related there was obstruction from a constricting band.

Dr. W. E. Porter thought the most important question which confronted us in peritonitis was whether it should be treated medically or surgically. As a rule too much time was lost with medical treatment before the case was turned over to the surgeon for him to obtain the best results. He thought that in septic peritonitis the pulse was a better guide to the severity and character of the disease than the temperature. One should be prepared to make an immediate microscopical examination of pus found in order to judge of its virulence.

Dr. Ralph Waldo thought the physical signs revealed by palpation afforded a better basis for diagnosis than the rational symptoms. Too much stress had been laid on the facies. He had known patients to die whose facies had been pronounced good, and others to recover whose facies had been pronounced bad.

Dr. R. A. Murray reminded the speakers that the paper had to do with diagnosis rather than treatment. How were we to tell when a peritonitis ceased to be local and became general? There were three indications: 1. Shock, for when the peritonitis ceased to be local there was always profound shock. 2. The facies; the mouth was drawn down, the features pinched, there was pallor or a pinkish, almost cyanotic hue. 3. The pulse became more tense. Further, in general peritonitis the pain was diffuse, not localized. Then there were, in local peritonitis, certain physical signs—tumor, etc.

Dr. Skinner, delegate from the Queens County Medical Society, had observed that where a case of peritonitis was about to prove fatal, the temperature fell to subnormal rather than rose. Referring incidentally to appendicitis, he said there was not always absence of some foreign body, for he had himself, when a student years ago, seen one man die after eating of beans, and a bean was found in the appendix, and in another instance the appendix contained an apple seed.

The Surgical Technique of Craniectomy: Demonstration of a New Method.—Dr. Seneca D. Powell read

a paper on this subject. In passing he might say that his experience had confirmed him in the opinion that craniectomy for microcephalus and its attendant idiotic state, if performed before the fourth year, would yield an ample reward.

The conclusions arrived at in the paper were based on fourteen cases with seventeen operations. The first was made in March, 1891, the last in March, 1895. The children ranged in age from two to thirteen years. In the first two cases he used a bone forceps, conductor's punch, and gouge ; upon the remainder he used the electric saw which had been made for him by Ford, and which he demonstrated on bone. There had been one death in a child of thirteen, death having been due to the shock of the operation. The duration of the operation had been only twenty-two minutes. The other patient operated upon by the conductor's punch also suffered greatly from shock, but fortunately recovered. It had been generally supposed by surgeons that the great mortality attending this operation in the hands of most operators was due to its long duration. When, after his first operation, Dr. Powell found his hands studded with blood-blisters from the use of the instruments his thought was directed to another cause. All were familiar with the effect of an innumerable number of successive blows upon a nerve, even though the percussion were hardly perceptible at the time. For instance, the effect of riding a bicycle over cobblestones was to leave the hands numb for a time. The conductor's punch produced a series of concussions upon the meninges and brain, and the effect seemed to be exaggerated in these cases by the fact that the bones were harder and the brain pressed outward more forcibly than in the normal state.

The author had conceived the idea that the operation might be deprived of much of its risk if it could be performed in a manner to overcome this series of concussions, and consequently he had had the electric saw constructed. It differed from the one made by the late Dr. M. Josiah Roberts some years ago in that the motor giving the power was not combined with the saw ; thus the saw was much lighter and could be handled with the ease of a dentist's drill. The membranes of the brain were protected by a thin strip of metal introduced beneath the skull through trephine openings. Prior to the operation the skull was shaved, and hemorrhage was obviated by a bandage encircling the skull horizontally three or four times and a strip of rubber adhesive plaster drawn tightly over it. There had been practically no loss of blood except that retained in the flap by the bandage. The scalp having been turned back, the trephine openings made, the latter were joined by two courses with the saw, removing a strip about half an inch broad and perhaps five inches long. To avoid making the incision which was parallel with the longitudinal sinus so long as to encroach on the frontal bone, he lengthened it by carrying its extremities down a distance over the side of the head. The edges were afterward made quite smooth with the bone-scoop. The scalp was then united and the bandage removed, and a dressing applied, which was left on a week or ten days. Shock from the operation with the trephine and electric saw seemed absent, and the patients had done as well apparently as if they had only been under ether. They left the bed the fifth or sixth day. It would be observed that no death had attended its use, which was on twelve patients.

Craniectomy in Itself Useless.—Dr. C. L. Dana expressed surprise and gratification at Dr. Powell's low mortality from craniectomy. He believed that at one time it had been so fatal here that it had been practically abandoned, without regard to the question of ultimate benefit. So far as he knew, no surgeon in the world had had as great success as Dr. Powell.

Dr. Dana had formed some rather positive opinions with regard to the therapeutic value of the operation. In the first place, we must abandon the idea entirely that craniectomy was intended for microcephalus, serving to make room for the brain to grow in. While there were cases of microcephalus, it was not because of premature ossification of the bones, but rather because of deficient brain development. To remove a strip of bone which should become replaced by cicatrix would hardly help the growth of the brain. But a large number of cases in which the operation was performed were not cases of microcephalus, but of lobar atrophies, cysts, etc. It seemed to him absurd to take away a piece of bone with the hope that it would assist the growth of a piece of sclerotic and atrophied brain tissue.

The ground had been well debated by Bourneville, of Paris, who had collected a large number of cases, and apparently shown that the operation was without practical use. On this point, however, Dr. Dana differed from Bourneville, for he had himself seen some benefit from craniectomy, and in seeking for an explanation he had come to the conclusion that it was based on a change of education and discipline. These subjects had been pampered and spoiled. After craniectomy they were put to studying and to work with a view to mental improvement. Out of about a dozen cases of his own he had seen a great deal of good derived in at least four, and he believed the usual percentage of cases improved where the operation was considered indicated was thirty to forty out of one hundred.

Dr. Carter Cole said he had witnessed many of Dr. Powells's operations, and could testify to the perfection of the technique which had reduced the mortality almost to nil. He had been surprised and gratified, also, to observe how perfectly the bandage around the head had controlled hemorrhage, in spite of its supposed inefficiency as expressed in the books. If in the temporal fossa there was a depression, simply insert a pad at that point.

Dr. Bishop thought Dr. Dana had given the correct explanation of the benefit of craniectomy.

Dr. Leszynsky quite agreed with the last speaker that the benefit was not due to enlargement of the skull. A specimen was shown recently in which the cicatricial tissue which had formed in the space left by removal of the bone had itself made pressure upon the bone. In all cases of craniectomy witnessed by himself the patient had died with one exception, so that there had been no time to judge of ultimate benefit.

Dr. W. R. Townsend wished to know why Dr. Powell made this particular form of incision.

Dr. Powell replied that it was to avoid encroaching on the frontal bone. He believed the first case operated upon by him had been sent him by Dr. Dana with the diagnosis of microcephalus. He had conscientiously avoided operating upon cases without first receiving the sanction of a neurologist, and in fact all of his cases with one exception had been sent him by neurologists for operation, and where that was done he had regarded it simply as his duty to perform the operation without questioning its advisability.

The Income Tax.—At the request of the chairman of the Board of Censors, the counsel for the Society, Mr. Taylor, sent a written opinion concerning the income tax in relation to physicians. A physician's office, or that part of his dwelling used as an office, and not the whole house, was exempt in estimating his income.

Who are Prescribing Druggists?—Dr. Frank Van Fleet referred to the action of the Society at its last meeting, calling for the prosecution of prescribing druggists. He wished to know whether persons advertising to fit glasses for errors of refraction did not also violate the law regulating the practice of medicine. The advertisement of one firm of this kind was in the county directory, and he moved to have it expunged. By amendment the matter was referred to the comitia minora with power.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, February 1, 1895.

HENRY F. WALKER, M.D., PRESIDENT, IN THE CHAIR.

Large Chancre of the Lip.—DR. ROBERT ABBE, who was detained until late, sent a patient with the following note of the case: A very decent Swedish girl, married six weeks, had come to him for removal of a cancer of the lower lip, which her physician had been lancing and leeching without benefit. At sight he diagnosed chancre of the lip, which was verified by a faint macular rash, now scarcely visible. The large size of the lesion and its rarity in this situation were his excuses for showing the case.

DR. E. L. PARTRIDGE said he thought the lesion must be chancre, but he could feel no sublingual glandular enlargement. For several years he had attended the Skin and Venereal Out-door Department of the New York Hospital, during which time four or five cases of chancre of the lip came under his observation, and in all early involvement of the sublingual gland was quite characteristic. Regarding infection with syphilis in unusual situations, he recalled a case, reported by Dr. Bangs, of a clerk who had chancre of the tonsil, the cause of which was probably the use of the same pencil used by another clerk at his side, both of them being in the habit frequently of putting the pencil into the mouth. It was learned afterward that his fellow-clerk had syphilis.

DR. BRYANT remarked that the unusual size and sensitiveness of the chancre were probably due to the various forms of local treatment applied before Dr. Abbe had seen the patient.

Notes on Intra-venous Coagulation, with Special Referenee to Thrombo-phlebitis.—DR. W. GILMAN THOMPSON read the paper. (See p. 449.)

Scurvy and Lemon-juice.—DR. VIRGIL P. GIBNEY, referring to the case mentioned in the paper in which lemon-juice had not been found necessary for the relief of scurvy of the gums, said he had had a similar experience in scurvy complicating joint troubles. A change of diet had been sufficient to cause the disappearance of the gum symptoms, without the use of lemon-juice. In talking with some friends who had seen a good deal of scurvy, he had learned that they hardly ever employed lemon-juice in the scurvy of children.

DR. PEABODY expressed his deep interest in the paper, and said he thought we were yet hardly ready to reach a definite conclusion with regard to intravenous coagulation and thrombo-phlebitis. From a clinical basis he was somewhat disposed to think that sluggishness of the circulation had something to do with it, yet it must be admitted that the seat of the changes was not always in the most distant arteries.

DR. BRYANT thought that in cases of trauma coagulation was due in some way to injury of the walls of the vessel. An illustrative case had come under his observation recently. A man, forty-two years of age, had sustained an injury of the thigh, which was followed by tenderness, hardness of the limb below the site of injury, by constitutional symptoms which led him to believe there was beginning phlebitis. On incision he found blood coagulated in the veins. He thought the criticism made in the paper, upon the application to the limb of the Esmarch bandage, a proper one. At all events, he would himself hesitate to apply it without placing some soft material beneath it.

DR. BEVERLEY ROBINSON had recently had the blood carefully examined in a case of typhoid fever complicated by the formation of a thrombus in a large vein of the lower limb, but the result was negative; the blood seemed to be in normal condition. Lately he had thought it advisable to withdraw some blood from a patient in the second stage of pneumonia, and it was noticed that it showed no tendency to coagulation. He queried whether that fact had anything to do with grippal pneumonia, which was probably the form of pneumonia this patient was suffering from. Doubtless all would be glad to learn of some therapeutic measure which would tend to prevent coagulation of the blood. Some years ago there was a belief that the ammonia salts, particularly carbonate of ammonia, had this tendency. Dr. Robinson did not know whether there was any real basis for this belief, yet he was inclined to give the carbonate of ammonia to patients suffering from pneumonia or typhoid fever, and seeming to be in danger of death from coagulation of the blood, more particularly in the heart. He had thought of this drug to-day in a case of amputation of the shoulder in a person who had been run over by a locomotive. The condition was such that they dared not remove the patient from the operating-table for four or five hours, and stimulants were constantly used. Suddenly there came considerable difficulty of breathing, Dr. Robinson thought of heart coagulum and of giving carbonate of ammonia, but refrained from interference with the surgeon's course. He would ask Dr. Thompson whether there was any particular drug which he would use under similar circumstances aside from ordinary stimulants.

DR. THOMPSON replied that before Dr. Robinson's arrival he had spoken of the influence of salts in preventing coagulation outside the body, but when given by the stomach they proved ineffectual. For a fuller statement of the case, see the paper.

DR. PEABODY remarked that Bartholow recommended the ammonia salts, not to prevent coagulation, but to dissolve a clot which might have formed in the heart. He believed there was no experimental proof of the efficacy of the method.

DR. THOMPSON said there were many salts which when added to the blood in large amount would prevent coagulation, but added in small amount they would favor it. It was practically impossible to use them in quantities sufficient to be of value.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

INFLUENZA—EXTENSION TO PROVINCES—MORTALITY—TREATMENT—VACCINATION COMMISSION—MR. TOM SMITH—A NEW DANGER DISCOVERED IN FROST—NERVOUS AFFECTIONS—SYPHILIS—DEBATE AT MEDICO-CHIRURGICAL SOCIETY.

LONDON, March 23, 1895.

INFLUENZA is still with us, but the improvement I anticipated last week is shown to exist in the week's returns of deaths. From 473, the highest weekly mortality in London, as stated in my last letter, the deaths fell during last week to 349. But even this number is a record, for it is higher than the highest in the last two epidemics. The mortality among the aged was, of course, most noticeable, 186 of the deaths being those of persons over sixty, and 47 had reached eighty. The deaths from all diseases of the respiratory organs fell from 1,366 to 1,031, but the last figure exceeds our corrected average by more than 500. The epidemic has been general throughout the country, but some towns have suffered excessively. Our London death-rate was 41.8 per 1,000, and Brighton showed no less than 48. Part of the last number is attributed to the influx of persons hoping by a visit to the sea to escape the disease, but who carried the infection with them.

Of course, the doctors have been affected in large numbers. All seem to have been very busy, and some

have stuck to their work after they ought to have been in bed. The consequences in not a few cases have been far more serious than if they had adopted the treatment they enjoined on their patients.

Nurses also have been in great request, and the demand could not at one time be supplied. In one case in which I was concerned, the patients sent twelve telegrams before procuring a nurse.

The treatment of influenza has naturally occupied much attention, and drugs, new and old, are advocated by enthusiasts. The general feeling of therapeutists is, however, to avoid too active treatment, and rely upon rest in bed in an even temperature. Afterward, the intense depression often called weakness leads many to sanction the free use of alcohol. Probably much mischief has been caused by this. More cautious men find small doses of quinine with strychnine a great help, and prefer it to wine or other form of alcohol.

The Royal Commission on Vaccination reassembled on Wednesday, but did nothing except pass a resolution regretting Sir W. Savory's death. As they had not met for five months, they cannot be accused of haste. They are more likely to be pointed to as exemplifying the practice of "how not to do it."

Mr. Thomas Smith, surgeon to St. Bartholomew's Hospital and a favorite teacher, has been appointed to succeed Sir W. Savory as surgeon extraordinary to the Queen. Barts still is in the front in court favor.

We are now enjoying genial spring weather, so may perhaps bear with more equanimity than during the frost the official statement that the cold had a pernicious influence on our water. When we could scarcely get any water to cook with, few people troubled about the great water question except to execrate the companies and demand the forfeiture of their monopoly. The present revelation as to the quality is calculated to create a scare. The frost prevented the filters working—that is the pith of the Registrar-General's figures. Water which in December contained 6 microbes per cubic centimetre, in February had 286. The increase in other cases was still more remarkable, *e.g.*, from 48 to 4,944, and from 50 to 5,200. In another case the number rose to 6,260, when unfiltered Thames water had only 720. How the frost makes the filtration such an aggravation of the impurity it may not be easy to determine, but obviously the subject demands immediate attention in the interest of the community.

The discussion on the nervous affections of syphilis at the Medico-Chirurgical Society, which extended over two evenings and drew forth some eminent speakers, seems to have drawn attention to the fact that these complications may occur early. This has been a familiar fact to the few for a long time, but it would appear that many, if not the majority, regarded nervous complications as only occurring late. In some cases objection has been taken to a diagnosis of syphilis, on the ground that the secondary stage was too early for the nervous affection, and yet some of us have been well aware for many years that this notion was an error. The debate will have done good if only it familiarize the profession with the fact that nervous affections may occur in the early stage of syphilis. In fact, the acute nervous complications are most frequently met in the secondary period, while the more chronic affections are more likely to begin in the tertiary stage. This was taught long ago by Erb, and ought by this time to have become generally known.

Physicians in Evening Dress.—A correspondent of one of the daily papers expresses his indignation because some of the physicians "in the 400" make it a practice to wear evening dress after six o'clock in the evening. He doesn't say how he would like to see them attired, but he could hardly expect them to don pajamas at that early hour.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 6, 1895.

	Cases.	Deaths.
Tuberculosis	182	87
Typhoid fever	4	1
Scarlet fever	128	23
Cerebro-spinal meningitis	2	2
Measles	189	16
Diphtheria	233	34

The Death of the Czar caused an advance in the price of benzoin, a gum that is largely used as an ingredient of the incense used in the ceremonies of the Greek Church.

The Oyster-typhoid Fever Scare in England is said to have ruined the sale of the bivalve this winter. As oysters cost about eight cents apiece in that afflicted country, there is not much danger to the ordinary individual from this source.

The University of Naples has been closed by order of the Italian Government, because of continuous rioting among the students, who objected to some reforms in the curriculum.

Catholics in England have been dispensed from fasting during Lent on account of the prevalence of influenza.

BOOKS RECEIVED.

THE PHYSICIAN'S VADE MECUM. Being a Handbook of Medical and Surgical Reference, with other useful Information and Tables. By Sebastian J. Wimmer, M.A., M.D. With additions by Frank S. Parsons, M.D. 16mo, 483 pages. Price, $1.00. Published by The Medical Publishing Co., Philadelphia, Pa.

PATHOGENETIC MATERIA MEDICA, BASED UPON DRS. HUGHES AND DAKE'S CYCLOPÆDIA OF DRUG PATHOGENESY. By the Medical Investigation Club of Baltimore, Md. 8vo, 347 pages. Price, $2.00, net; $2.17 by mail. Publishers, Boericke & Tafel, Philadelphia, Pa.

THE MEDICAL ANNUAL AND PRACTITIONER'S INDEX. By various editors. 8vo, 751 pages. Thirteenth year. Illustrated. Published by John Wright & Co., London, England. Price, 7s. 6d.

THE EVOLUTION OF THE DISEASES OF WOMEN. By W. Balls-Headley, M.D. 8vo, 375 pages. Illustrated. Published by Smith, Elder & Co., London, England. Price, 16s.

DEGENERATION. By Max Nordau. 8vo, 560 pages. Published by D. Appleton & Co., New York City. Price, $3.50.

ECTOPIC PREGNANCY. By J. Clarence Webster, M.D. 8vo, 300 pages. Illustrated. Published by Young J. Pentland, Edinburgh and London.

A MANUAL OF BANDAGING. Adapted for Self-instruction. By Dr. C. Henri Leonard. 8vo. 159 pages. Illustrated. Published by the Illustrated Medical Journal Co., Detroit, Mich.

THE ELEMENTS OF PATHOLOGICAL HISTOLOGY. With Special Reference to Practical Methods. By Dr. Anton Weichselbaum. Translated by Dr. W. R. Dawson. 8vo, 475 pages. Illustrated. Published by Longmans, Green & Co., London, England. Price, $7.50.

MANUAL OF CHEMISTRY. By Dr. W. Simon. Fifth edition, thoroughly revised. 8vo. 502 pages. Illustrated. Published by Lea Brothers & Co., Philadelphia, Pa.

A COURSE OF ELEMENTARY PRACTICAL BACTERIOLOGY, including Bacteriological Analysis and Chemistry. By Dr. A. A. Kanthack and J. H. Drysdale, M.B., M.R.C.P. 12mo, 181 pages. Illustrated. Published by Macmillan & Co., New York City. Price, $1.10.

SUGGESTIVE THERAPEUTICS IN PSYCHOPATHIA SEXUALIS; with Especial Reference to Contrary Sexual Instinct. By Dr. A. Von Schrenck-Notzing (Munich, Germany). SOME EXPERIENCES IN THE PRODUCTION AND USE OF DIPHTHERIA ANTITOXIN.

BY HERMANN M. BIGGS, M.D.,

PATHOLOGIST AND DIRECTOR OF THE BACTERIOLOGICAL LABORATORIES OF THE HEALTH DEPARTMENT OF NEW YORK CITY.

THE principles underlying the blood-serum therapy had been fully established so long ago as 1892 through the researches of Behring, Kitasato, Ehrlich, Roux, and others, but they were not reduced to a practical form, so that the method was available for the treatment of disease until 1894.

During the interval, Behring, Ehrlich, Roux, and others, together with Aronson, were diligently seeking to make this method available for the treatment of diphtheria.

Early in 1894, a small quantity of antitoxin produced by Aronson was placed at the disposal of the Health Department for experimental purposes, but the observations made with it were not very satisfactory.

In June, 1894, it was my privilege to watch the work being done in the Institute for Infectious Diseases in Berlin, to follow carefully the production of antitoxin there, and to obtain from conversation the personal impressions as to its value of the numerous staff of distinguished medical men connected with the Institute.

I found then that there was no shadow of doubt in the mind of any of these observers as to the specific value of antitoxin in the treatment of diphtheria. At this time about four hundred cases had been treated with serum produced in the Institute under the direction of Behring, Ehrlich, Wasserman, and Kossel. Exceedingly favorable results had been obtained in this series of cases. Other cases in Berlin had been treated by Aronson, or with the serum produced by Aronson, and a still larger number by Roux in Paris.

At this time, and for some months later, very wide differences of opinion existed between Behring, Aronson, and Roux, as to the best methods for the production of immunity in animals and as to the kind of animals best suited for the purpose. While horses, cows, sheep, goats, and dogs were all being employed at the Institute for Infectious Diseases, still the belief at that time was that goats possessed many advantages over other species of animals. Behring believed that the more susceptible any species of animals was to the poison of diphtheria, the more highly could they be immunized and the more valuable was the serum which they produced.

Goats are extremely susceptible to the diphtheria poison, are difficult to immunize, but, when thoroughly immunized, produce a serum of high grade.

The remarkable results which Roux had obtained were not generally known until after the International Congress held in Buda-Pesth in September, and it was not until after the contents of his paper were widely published that the new treatment of diphtheria began to attract almost universal attention.

During my stay in Berlin, I requested by letter Dr. William H. Park, assistant director of the Bacteriological Laboratory of the Health Department, to commence the growth of cultures of the diphtheria bacilli for the production of toxins, as at that time it was thought necessary to grow cultures for six or eight weeks, in order to produce toxins active enough for the inoculations. This was done, so that, upon my return in August, the process of immunization of animals might be immediately begun.

No little difficulty was experienced in obtaining sufficiently virulent cultures of the diphtheria bacillus, and still more difficulty was found in obtaining solutions of the toxins of adequate strength, so that finally the inoculation of animals under the supervision of the Health Department was not begun until early in October, 1894.

At first two goats, and then two sheep, three dogs, and a cow were inoculated, and some days later the inoculation of horses was begun. The number of horses was rapidly increased, and by the middle of December thirty-five or forty horses were under treatment.

After the publication of Roux's paper, such favorable results were reported as having been obtained with horses, that the inoculation of the other animals was soon suspended.

During all the time that the work was being done by the Health Department, Dr. T. Mitchell Prudden, consulting physician to the Department in the Division of Pathology, Bacteriology, and Disinfection, has been in constant communication with the physicians engaged in the work, and has assisted it in every way. A number of horses have also been treated under his personal direction by Dr. C. B. Fitzpatrick, and it was one of these horses whose serum was first tested as to its antitoxin value. The serum proved to have an immunizing power of something more than one in fifty thousand, and as the animal was otherwise in rather a poor physical condition, Dr. Prudden determined to destroy it in order that as large an amount as possible of serum might be immediately at disposal, as at this time the imported serum could be had only in the very smallest quantity.

Serum from this horse was tested and bottled to the amount of four litres or more, and was very generously placed at the disposal of the Health Department by Dr. Prudden, and employed under the supervision of the Health Department for the treatment of diphtheria both in the Willard Parker Hospital and among the poor outside the hospital. In behalf of the Department, I desire to express the very great obligations which the Department and its representatives owe to Dr. Prudden and to the Pathological Department of Columbia College, of which he is the director, for the great assistance which has been afforded in this work.

The serum from other horses was not tested for several weeks after the first one, so large an amount having been obtained from it. As the treatment had been continued for so short a period it was deemed wiser, as long as this serum was at the disposal of the Department, to postpone the testing of other horses until it had been exhausted.

The first serum was put in use about January 1st, and since that time the amount of serum at our disposal has rapidly increased in quantity and improved in quality.

The assistance afforded by the Executive Committee of the *New York Herald* Antitoxin Fund has very greatly facilitated the work of the Health Department, and has made the production of the serum in larger

quantity and more rapidly than would otherwise have been possible.

The cases of diphtheria treated with antitoxin under the supervision of the Health Department comprise two series: the first, those treated in the Willard Parker Hospital, and the second, those treated outside of the hospital, chiefly among the poor in the tenement-house districts, by Health Department inspectors, detailed from the division of Bacteriology for this purpose.

The second series includes those cases treated by Sanitary Inspectors Drs. Walter F. Bensel, John H. Huddleston, Henry F. Koester, H. J. Ennis, William J. Pulley, and a few which were treated by Dr. William H. Park and the writer. There were 255 of these cases, with 40 deaths, a mortality of 15.69 per cent. Of these 50 are recorded as having been mild, 76 of moderate severity, 96 severe, and 42 severe and septic. Of 252 cases noted, in 21 the larynx was alone involved; in 116 the pharynx, or tonsils, or both, were involved; in 57 the pharynx and nares were involved; in 41 the larynx and pharynx were involved, and in 17 the larynx, pharynx, and nares were all involved. One hundred and seventy-three cases were five years of age or under, and among these 33 deaths occurred, a mortality of 19.07 per cent.; 82 cases were over five years of age, and among these 7 deaths occurred, a mortality of 8.53 per cent. On the first day of the disease 30 cases were treated; deaths, 2; mortality, 6.66 per cent. On the second day 77 cases were treated; deaths, 7; mortality, 9.09 per cent. On the third day 67 cases were treated; deaths, 11; mortality, 16.41 per cent. On the fourth day 31 cases were treated; deaths, 7; mortality, 22.60 per cent. On the fifth day, or later, 46 cases were treated; deaths, 13; mortality, 28.25 per cent.

Of the 40 deaths occurring in the whole series 15 took place in less than twelve hours after the serum was administered. These cases were hopeless, and most of them were moribund at the time of the injection. They were injected by the inspectors, for the most part under protest, because the physicians in attendance or the friends of the patients insisted that antitoxin should be administered. These may fairly be excluded from consideration in judging of the results of the new treatment, as death occurred before sufficient time had elapsed for the serum to produce its effect. Deducting them, we have 240 cases with 25 deaths, or a mortality of 10.4 per cent.

Among the cases treated on the first day of the disease two deaths occurred. The first death occurred in a child a little over two years old, suffering with very severe laryngeal diphtheria. This case was injected and intubated within the first twenty-four hours of the illness; death was only delayed by the administration of the antitoxin and took place on the tenth day from broncho-pneumonia. Dr. Bensel, who treated this case, says: "I feel absolutely certain that death would have taken place in this case within the first forty-eight or seventy-two hours of the disease if antitoxin had not been administered."

The second death was also the result of severe laryngeal diphtheria with stenosis; it occurred in a child thirteen months old. The child was intubated, and died of stenosis on the third day after the removal of the tube.

Of 77 cases treated on the second day 7 died, a mortality of 9.09 per cent. Three of the fatal cases were moribund at the time of injection and died in less than twelve hours.

Deducting these, there remain 74 cases and 4 deaths, a mortality of 5.04 per cent.

Of 67 cases treated on the third day 11 died, a mortality of 16.41 per cent. All of the fatal cases in this group, with one exception, had laryngeal diphtheria, or laryngeal and pharyngeal.

In 4 of the fatal cases the patients were moribund when antitoxin was injected; 1 died an hour after injection; 1 four hours after; 1 was complicated with scarlet fever and septic poisoning, was pulseless when injected and died a few hours later; and 1 was suffering from severe laryngeal stenosis and broncho-pneumonia, was not intubated, and died from unrelieved stenosis, with high temperature, a few hours after the injection.

In one case treatment was discontinued for four days because of the objection of friends, although decided improvement had followed the first injection. It was then resumed, but death from cardiac paralysis occurred later.

These 5 cases may be fairly excluded from consideration. We then have 62 cases treated on the third day, with 6 deaths, or a mortality of 9.68 per cent.

Of 31 cases treated on the fourth day 7 died, a mortality of 22.06 per cent. Six of the fatal cases suffered from laryngeal diphtheria, and one from naso-pharyngeal. Three of these were moribund when injected and died within less than twelve hours; one of the remaining seven had been intubated; the child had greatly improved, and on the ninth day the tube was removed; the child died suddenly from stenosis one-half hour later, after the physician in attendance had left.

Excluding the 3 moribund cases from this group, there remain 28 cases, with 4 deaths, a mortality of 14.28 per cent.

It does not seem desirable that any special analysis should be made of the cases which were treated on the fifth day or later, as all of the evidence goes to show that, under most circumstances, only moderate benefit can at best be obtained from the use of antitoxin in such cases, and although, occasionally, striking results follow the administration of antitoxin, even late in the disease, yet this result must be considered as exceptional.

If we consider again the whole series, after deducting those which were treated on the fifth day or later, we have 209 cases, with 27 deaths. Of the 27 fatal cases death occurred in twelve hours from the time of injection in 12. Deducting these and there remain 197 cases of diphtheria treated before the fifth day, with 15 deaths, a mortality of 7.79 per cent. Of the 197 cases in this group 126 were five years of age or under, and of these 11 died, a mortality of 8.72 per cent.

In judging of the results obtained in this series, it must be kept in mind that almost all occurred among very poor people in the tenement-house districts, where, in many instances, the care was not of the best, and where often but little in the way of other treatment was employed. With the exception of possibly a half dozen, the diagnosis was established in every case by the demonstration of the presence of the diphtheria bacilli in the throat, so that there can be no doubt as to the nature of the disease which was being treated.

Cases Treated in the Willard Parker Hospital.—I am indebted to Dr. W. L. Somerset for the data regarding cases treated in the hospital. Far less favorable results were obtained in these cases than in those treated outside. Hospital cases are, in general, severe; usually do not come under observation until relatively late in the course of the disease, and often then are suffering from serious complications.

From January 1st to date there were 164 cases of diphtheria in the hospital treated with antitoxin, with 45 deaths, a mortality of 27.4 per cent. During the first three months of 1894, 146 cases were treated, with 47 deaths, a mortality of 32.1 per cent. During January, 1895, however, the antitoxin was weak. From February 1st serum equal to Behring's No. 1, or better, was at command. After this time 115 cases were treated, with 31 deaths, a mortality of 26.9 per cent. Excluding 2 cases that died within twelve hours after the administration of the serum, we have 113 cases, with 29 deaths, a mortality of 25.6 per cent.

Of the 115 cases, in 44 the larynx was involved, and in 71 the pharynx, or the pharynx and nares.

In the pharyngeal and nasal cases there were 10

deaths, or a mortality of 14.08 per cent. In 1894 (during the first quarter) there were 104 pharyngeal and nasal cases, with 25 deaths, or a mortality of 24.03 per cent. Of the 44 laryngeal cases 21 died, a mortality of 47.7 per cent. Twenty-eight of the 44 cases were intubated, and of these 16 died, or a mortality of 57.1 per cent. Excluding from these 28 cases 9 (of which 7 died) which were treated with antitoxin on the fifth day or later, and there remain 19 cases of laryngeal diphtheria with intubation, and 9 deaths, or a mortality of 47.3 per cent.

In 1894 16 cases, *all included*, were intubated, with 13 deaths, a mortality of 81 per cent.

Sixteen of the laryngeal cases were not intubated, and of these 5 died. If we exclude from this class the cases treated on the fifth day or later, we have 11 cases, with 3 deaths, or a mortality of 27.27 per cent. In 1894, during the first three months, there were 26 laryngeal cases which were not intubated, and of these 9 died, a mortality of 34.61 per cent.

During the period referred to in 1895, all cases of *diphtheria* admitted to the hospital were treated with antitoxin, and are included in this list. Cases in which the diphtheria bacilli were not found were not included.

Notes on Some of the Fatal Cases.—Fatal cases injected on the second day of the disease :

Case I.—Katie J——, two years of age, admitted with mild tonsillar and pharyngeal diphtheria and marked general bronchitis. Death occurred thirty days after admission from extensive broncho-pneumonia. The autopsy also showed general miliary tuberculosis.

Case II.—Meyer A——, aged seventeen months, admitted with diphtheria bacilli, and no visible membrane in throat. Right eye showed membrane on lids and suspicious bacilli. Eye made good recovery. Died thirty-two days after admission with broncho-pneumonia. Child ran normal temperature two weeks previous to the onset of the pneumonia.

The autopsy showed lobar pneumonia involving the right upper and middle lobe.

Fatal cases injected on the third day of the disease :

Case I.—S. D——, eighteen months of age ; case admitted with extensive pulmonary œdema and marked stenosis ; was then cyanotic, unconscious, and pulse could not be found. Intubated at once. Artificial respiration. Consciousness regained. Color improved, but the lungs continued full of fluid, and the child died in twenty-four hours. Membrane visible on left tonsil only.

Case II.—Becky C——, two and one-half years of age, admitted with severe stenosis. She was immediately intubated, and did well for eight days, but then developed broncho-pneumonia, and died twelve days after admission. Autopsy showed extensive broncho-pneumonia.

Case III.—Martin Jacob S——, two and a half years of age, admitted with severe stenosis and considerable tonsillar and pharyngeal membrane. Nose partially obstructed. Cervical adenitis. Broncho-pneumonia. Lived forty-eight hours after admission. Was intubated and tracheotomized. Considerable membrane coughed up through tracheotomy tube.

Case IV.—Sarah L——, two years of age, admitted with slight tonsillar deposit and slight stenosis, prolapse of the rectum, and marasmus. Probable broncho-pneumonia. Lived thirty-two days. Temperature 99° to 101° F.; respiration, 24 to 40. Coarse râles, roughened breathing sounds persisted over both sides of chest behind. Throat clear from membrane in three days. Croup did not persist.

Case V.—Florence H——, eight months of age, admitted with mild tonsillar diphtheria and slight stenosis. Sixteen days after admission a cervical abscess was opened. Twenty-eight days after admission, there was a purulent discharge from both ears. Temperature went up after the ears began to discharge. The child became restless, cried constantly, and refused nourishment. Death occurred seven days after rupture of the otitis, thirty-two days after disappearance of membrane, and twenty-days after disappearance of diphtheria bacilli from pharynx.

Case VI.—Elsie G——, two years of age, admitted with well-marked tonsillar and pharyngeal deposit and stenosis. Intubated ; stenosis relieved ; temperature, 106° F.; respiration, 50. No physical signs. Appearance of membrane in pharynx would indicate that case was more than three days sick. Died the third day.

Two other fatal cases died in less than twelve hours after the administration of antitoxin. These cases were moribund on admission.

One other case showed at the autopsy a general miliary tuberculosis, and three showed pulmonary tuberculosis with more or less broncho-pneumonia.

Two other cases had scarlet fever and died some time after removal to North Brothers Island.

In a number of other fatal cases death occurred some days after the disappearance of the membrane, and the autopsy revealed a broncho-pneumonia.

In speaking in general of the value and results of the treatment I wish to refer to some extracts from a report made to me by Dr. Walter F. Bensal. He says :

"The total number of cases treated by me was 82. Of these 70 recovered, 12 died, making a mortality for all ages of about fifteen per cent. Sixty of these showed immediate and marked improvement after the administration of the serum. In 6 there was marked improvement, which was, however, developed very slowly. It may or may not have been due to the antitoxin. In the remaining 16 no benefit could be attributed to the antitoxin directly. In 34 of the 82 cases the prognosis was exceptionally bad, making an estimated probable mortality of forty-one per cent. without antitoxin, which contrasts very favorably with the actual mortality of fifteen per cent.

"In 12 cases treatment was begun on the first day, and all showed an immediate improvement. In 25 cases treatment was begun on the second day of the disease, and all but 3 were promptly benefited. In 17 cases treatment was begun on the third day, with an immediate result in 13. Of 11 treated for the first time on the fourth day only 7 were benefited. For the fifth day only 4 out of 8, for the sixth day only 1 out of 3, and for the seventh day only 1 out of 4 had an immediate benefit from the antitoxin. Of the 2 cases treated for the first time on the tenth day no direct result was obtained. This shows how important it is to employ antitoxin early, as few or no striking results occur when the fifth day of the disease has passed before beginning treatment.

"In my experience the effect of the antitoxin on the false membrane has almost always been very marked. Even when little or no improvement in the general condition has resulted the advance of the membrane has been checked and a marked disposition to thin out and disappear has been developed.

"**After-effects of Antitoxin.**—In 82 cases of true diphtheria 33 remained absolutely free from any annoying after-effects. In 22 of the remainder urticaria was developed, varying in degree and extent. In some it was limited to the limb or limbs injected, and only caused slight annoyance for two or three days. In other cases it extended from head to foot, the irritation being very intense and lasting a week or more. It made its appearance from three to ten days after the injection.

"In 8 cases an erythema was developed, usually more or less confined to the locality of the injection, and making its appearance two or three days afterward. This was accompanied by more or less urticaria.

"One case of diphtheria (a rather mild form, but receiving a fairly large amount of serum in two doses) developed a general urticaria eight days after the second injection, the itching of which was almost unendurable. This lasted four days, but had hardly subsided before the patient, a woman, began to develop

pains, neuralgic in character, in the lower limbs, with some slight swelling of both knees. This condition grew worse from day to day, and soon all the joints of the lower extremities were swollen, painful, and stiffened, with a very marked hyperæsthesia of the skin. Loss of power was complete, so that she was unable to walk or even to stand. On the third day she also began to lose power in her upper extremities, so that she was unable to move in bed without assistance. The last muscles affected were those of the jaw, preventing mastication. On the eighth day the patient had several profuse hemorrhages from the nose, which recurred, but not so profusely, from time to time during the next week. About this time she began to regain power in her limbs, and in a few days was able to stand and then to walk with difficulty. It is now thirty-eight days since her attack of diphtheria, and she is still unable to walk more than a few blocks at a time. The lymphatic glands in her neck were more swollen and tender twenty-six days after her recovery from diphtheria than at any other time. They are still much swollen but no longer tender. A trace of albumin was found in the urine during the development of the complications.

"In 7 cases of false diphtheria, injected while awaiting the result of the culture, only 2 were exempt from after-effects. These after-effects were, in the main, much the same as in the cases of true diphtheria just mentioned, but were developed in a larger proportion, and were more marked in degree. One patient developed the same trouble as the case just described, but to a much more serious extent in every way. In addition she had several alarming hemorrhages from the uterus, and a temperature ranging from 100° to 104° F. Although the antitoxin was given on February 5th, she has not yet left her bed (March 10th). About two weeks ago she developed an acute synovitis of the knees, with fluid in both joints and in the pericardial and in one pleural cavity. I am hardly prepared to say, however, that all her trouble has come from the antitoxin." It should be said that in these cases large doses of a weak serum were employed.

In fatal cases treated by antitoxin no new anatomical lesions have been found. There is no positive evidence as yet to show that antitoxin in any case has produced or hastened death, although it may apparently, in rare instances, produce serious complications.

It is, however, comparatively common to have characteristic eruptions follow the use of this remedy, and sometimes apparently more serious complications, as described. The frequency of the rashes varies greatly, but they appear to be more common when antitoxin is administered in fairly large doses in mild cases. The eruption may take the form of an urticaria, or may be scarlatiniform or morbiliform in character. It may be local around the point of injection or general. The time of appearance varies from five to twenty days after the injection of serum, the average being about eight or ten days. It is usually accompanied by intense itching; there may or may not be elevation of temperature. Its duration varies from a few hours to four or five days or longer, but usually it disappears in about thirty-six or forty-eight hours.

In 129 cases treated in the Willard Parker Hospital there were rashes in 20. In 12 cases the rash was an urticaria, in 5 it was like that found in scarlatina, and in 3 it resembled measles.

In 21 out of 129 cases there was albuminuria, and in 6 there was paralysis, slight in amount. Two of the cases of albuminuria died with suppression.

The serum employed in the treatment of the cases reported here, with the exception of a few phials of Behring's and that referred to, received from Dr. Prudden, was produced under the supervision of the Health Department. It varied in strength from that first used, which contained 30 or 40 antitoxin normal units in each cubic centimetre, about one-half the strength of Behring's No. 1, to some of that last produced, which contained 300 antitoxin normal units in each cubic centimetre, equal to about twice the strength of Behring's No. 3.

The Health Department now has an abundance of high-grade serum, and is prepared to meet all demands arising from this city. It is administered under the supervision of the attending physician, free of charge among the poor of the city on application. It is also for sale when the physician prefers to purchase it and administer it himself.

It should be remembered, in judging of the results obtained in the treatment of cases of diphtheria with the diphtheria antitoxin, that the new remedy is a specific only against diphtheria toxæmia, and that it thereby increases cell-resistance, reduces inflammatory swelling, and arrests the extension of the membrane—only this. It does not restore already degenerated heart-fibres or kidney cells; it does not immediately relieve an impending asphyxiation from laryngeal stenosis, or neutralize a septic poisoning, or influence the temperature, or check the extension of a broncho-pneumonia. To be effective it must be administered early in the course of the disease, before complications have occurred or the effects of the diphtheria toxin on the tissue-cells have been produced. The earlier it is administered the more striking are the results produced and the more certain the cure. When not administered until the fifth day of the disease or later, or until a general bronchitis or broncho-pneumonia has occurred, or degeneration of the heart or kidney has been produced, or until the child is exhausted from struggling against an unrelieved stenosis, its influence for good is little or nothing, and deaths in such cases are not to be regarded as antitoxin failures.

It may be urged that no conclusion can be drawn from these results as to the value of the new treatment because diphtheria is of a mild type this year. This contention cannot be maintained, for there is no reliable evidence to this effect, and before the introduction of antitoxin in the treatment of diphtheria the mortality during the past year was as high as for the corresponding months of the previous year. During the same period, when these cases were being treated, the mortality among cases not treated with antitoxin, instead of averaging eight or ten per cent., was, judging from the Health Department reports, from twenty-five to thirty-five per cent.

While there can be no question that occasionally cases of uncomplicated diphtheria will die even when antitoxin is administered early in the course of the disease, yet in my opinion, with the curative serum at disposal, diphtheria, which has been the most fatal disease of infancy and early childhood, will be brought so completely under control, through the early administration of this remedy, that it will lose all of its terrors. How serious the complications may sometimes be we do not as yet know.

Statistics may or may not have much significance, and it may perhaps be justly said that, so far as New York is concerned, nothing decisive has as yet been shown by them as to the curative value of diphtheria antitoxin. I would add, however, that the results in individual cases are often far more convincing than the conclusions drawn from a large series of cases. All that is required to convince any sceptical observer of the efficacy of the serum is that he may watch the results in one single, severe, uncomplicated case of diphtheria, when the remedy is administered on the second or the beginning of the third day. They are sometimes most extraordinary, and seem to me to approach the miraculous more nearly than anything which has previously come under my observation in medicine.

5 West Fifty-eighth Street.

THE PREPARATION OF THE DIPHTHERIA ANTITOXIN,

And Some of the Practical Lessons learned from the Animal Experiments Performed in Testing its Value.

By WILLIAM HALLOCK PARK, M.D.,

NEW YORK.

The first step toward obtaining a supply of diphtheria toxin for the injection of the animals is to secure pure cultures of bacilli from a number of severe cases of diphtheria. The bacilli from these cultures are grown in bouillon for forty-eight hours in the incubator, and their virulence tested by injecting them into guinea-pigs. From the number tested as many as four or five of the most virulent cultures should be selected to inoculate the bouillon for making the toxin, for experience has taught that bacilli having equal virulence in guinea-pigs do not always produce the same amounts of toxin in bouillon. It has also been found that the bacilli in cultures from different cases vary greatly in the length of time the bacilli retain their full virulence. In making the original stock-cultures it is desirable to inoculate the bouillon in each of the tubes with bacilli from a number of colonies from the agar plates. The cultures thus obtained are more apt to be very virulent. The experiment of trying to increase the toxin-producing power of the bacilli by passing them through the bodies of a series of guinea-pigs has been carefully tried in the laboratory. Dr. Williams, who carried out the experiments, succeeded in considerably increasing the virulence of the bacilli from some of the cultures, and obtained in the broth in some of the tubes inoculated with these bacilli a stronger toxin than that from the broth inoculated with bacilli which had not passed through the bodies of animals. However, the strength of toxin varies so much in the bouillon in different flasks, even when made from the same culture, that we do not feel sure that the increased toxin production of the bacilli was due to this passage through the animals. The practice recommended by Roux, of inoculating the bouillon in each flask with a number of cubic centimetres of a recent and very virulent culture, has been followed as a routine practice. The flasks used for the preparation of toxin may be either of the ordinary varieties or may be arranged with tubes for the inlet and exit of air. We have found that bacilli grown in rather alkaline bouillon, in ordinary flasks loosely plugged with cotton, produce toxins about as strong, and nearly as quickly, as those grown in the bouillon to which a constant supply of moistened air has been added. Toxins, of which one-tenth of a cubic centimetre was sufficient to kill a 250-gm. guinea-pig in five days were produced in the bouillon in one-half the flasks in from two to four weeks. In some cases the toxins were twice the above strength, while in others, subjected to the same treatment, they were much weaker. When it is judged that the bouillon culture is sufficiently rich in toxin a few cubic centimetres are carefully removed with a sterilized pipette and the toxin solution thoroughly tested as to its purity and strength. If the cultures prove in the least contaminated they are, as a rule, discarded, but if merely too weak in toxin they may be replaced in the incubator for further development. If to an old bouillon culture one-half per cent. of carbolic acid is added, and the bacilli after being killed are allowed to soak in the bouillon, the amount of toxin in solution will be found for a time to gradually increase. The dead bacilli give up some of the toxin contained in their bodies to the bouillon. Before being injected into the horses the toxins are filtered.

Selection of the Horses.—For this purpose Dr. Gill, of the New York Veterinary College, procured, during the months of November and December, over forty young, perfectly sound horses. Most of these had some bad habit, such as kicking, balking, or running away, and were therefore purchased at very low prices. Before using they were all injected with mallein in order to exclude the possibility of glanders.

Since the laboratory force of the Health Department was increased, last January, I have had the help of Drs. Lambert and Fitzpatrick in the labor connected with the production of antitoxin in so many horses. These horses were purchased partly by the Health Department and partly by means of the fund raised by the *New York Herald*. The horses receive for their first injection, 2 c.c. of a toxin of which one-half a cubic centimetre would kill a 250-gm. guinea-pig, or an equivalent amount of stronger toxin. If the horses reacted sharply with fever, extensive local swelling and loss of appetite, the dose was not repeated until all these symptoms subsided. If the horses showed no reaction they were given, in two days, another dose of double the quantity. In the course of ten days the use of strong toxins was begun in all. Treated in this way the majority of the horses will be able to take 100 c.c. of strong toxin in a single dose at the end of from two to four months without showing any marked disturbance. A few horses are very sensitive and these are very difficult to accustom to the toxins. Among the forty injected seven have died.

At present there are ten horses containing sufficient antitoxin in their serum for the treatment of diphtheria, and a number giving serum of sufficient strength for purposes of immunization. One horse gives serum one-half stronger than Behring's No. 3; one gives serum equal to that of Behring's No. 3; two equal to Behring's No. 2, and five give serum equal to Behring's No. 1.

The Methods Employed in Bleeding the Horses.—The skin of the neck having been shaved and cleansed, the jugular vein is pressed upon low in the neck and caused to distend. Over the vein the skin is incised, and through this incision a sharp-pointed cannula is forced into the vein. The stream of blood is conducted, by means of a rubber and glass tube into sterilized Erlenmeyer flasks.

To me the great difference in the amount of antitoxin furnished by different horses which have received the same amount of toxin, and in the same doses, is of great interest. For instance, two horses started on November 4th had received by January 15th, 600 c.c. each of normal toxin; at that time the antitoxin strength of the serum of the first horse was equal to that of Behring's No. 2, while the serum of horse No. 2 was only one-fifth of that strength. On March 1st the strength of the serum from the first horse had risen to double that of Behring's No. 2, while that from horse two remained only one-eighth of that strength. Both of these horses had shown a moderate elevation of temperature after each injection, and both had shown only slight general disturbances. The better horse was slightly more sensitive than the other to the toxin. Both horses seemed to suffer but little under the treatment. An interesting experiment was now tried. As you know, several of the most valuable horses abroad died from attempting to procure a very high grade of serum by the injection of very large doses of toxin. We thought it best to let well enough alone, and so gave three of the best horses during the last month only very small doses of toxin. The tests just concluded show, unfortunately, that under this treatment the amount of antitoxin has begun to diminish, so that it seems here, as elsewhere, that nothing venture nothing have.

The Testing of the Antitoxin.—At present we use entirely Behring's method. His method possesses certain great advantages over that of Roux. First, by using toxins instead of the bacilli, we have a substance which remains of constant strength. As is well known, cultures of the living bacilli vary from day to day in their virulence. The bacilli contained in two tubes taken from

the same culture may after forty-eight hours possess very different amounts of virulence. To accurately test by Roux's method a large number of guinea-pigs must be used each time as controls, and even then the test is not as delicate as that of Behring's. We have found, on the other hand, that the diphtheria toxin kept in small flasks at a rather low and even temperature keeps for months of almost exactly the same strength. After a little while we are thus able to accurately determine the amount of toxin necessary to surely kill a guinea-pig of a given weight. In the course of a very large number of experiments in testing antitoxin, we have found that, whenever in a series the amounts of antitoxin injected have been too small to protect, the guinea-pig receiving the smallest amount of antitoxin has always been the first pig to die; the one receiving the next smallest amount being always the second to die. When the results obtained have been controlled by later trials we have found them substantiated in every case.

The serum from each bleeding is always tested as to its strength in antitoxin. This is absolutely necessary, as in the course of three weeks the strength of the serum may either greatly increase or diminish, and for this change there may be no ascertainable reason.

Therapeutic Hints from the Animal Experiments.—If in a guinea-pig very virulent diphtheria bacilli are rubbed upon a portion of mucous membrane which has been excoriated or cauterized, a disease very similar to diphtheria in man is produced. For two or three days the local changes develop, and then later the constitutional ones. Death follows in from four to five days. If, however, a guinea-pig thus treated has within a short time previously been injected with diphtheria antitoxin, slight local changes only develop and the pig recovers. The same results follow if sufficient antitoxin is injected subcutaneously within the first twenty-four hours after the infection. If the antitoxin is given too late no beneficial results follow. For instance, each of ten 500-gm. guinea-pigs was injected with ten times a fatal dose of diphtheria toxin—a dose sufficient to kill within twenty-four hours. Two of them received $\frac{1}{1000}$ c.c. of antitoxin serum, an amount of antitoxin equal to one-fifth of an antitoxin unit; four others received, twelve hours after the toxin injection, respectively, seven, fifteen, and thirty times the quantity of antitoxin received by the first two; finally, twenty hours after the injection of the toxin two pigs received seven hundred and one thousand five hundred times as much antitoxin as the two pigs first mentioned. The pigs receiving the minute dose of antitoxin at the same time as the toxin showed no bad symptoms whatever, while those receiving the very large doses twelve to twenty hours after the injection of the toxin all died. The large doses given twelve hours, and the immense doses given twenty hours after infection, and four hours before the expected death, produced no curative effect, the pigs dying at almost the same time with the pigs which received no antitoxin whatever.

Mixed Infection.—The experiments of Roux with mixed infection are so interesting in this connection that I need hardly apologize for giving them here in brief.

Four rabbits were tracheotomized and then injected in the trachea with a mixture of streptococci and diphtheria bacilli. One received at the same time a subcutaneous injection of antitoxin; the second an injection of twice that quantity six hours later, and a third five times the quantity twelve hours after the infection. The fourth received no antitoxin. The first rabbit was feverish and slightly sick for two days, no diphtheria developed, and the animal completely recovered. In the second diphtheria developed, progressed, and caused death in five days; in the third the disease progressed just as rapidly as in the fourth, which had received no antitoxin. All the fatal cases showed at autopsy the lesions of broncho-pneumonia, and the cultures showed streptococci to be present in the blood.

From animal experiments, then, we have these facts: A small but sufficient amount of antitoxin will certainly prevent animals from developing the lesions of diphtheria after they have been infected with the diphtheria bacilli alone, or mixed with streptococci if the serum is given before, at the time, or shortly after, the attempted infection. If, however, the injection of antitoxin is delayed too long it will not have any appreciable effect in preventing the progress of the disease. A longer delay is possible when the infection is due to diphtheria bacilli alone than when the bacilli are combined with the streptococci. After several months the effects of the injection of the antitoxin pass away, and the animals are as susceptible as before they received the injection. Another injection gives them immunity again for a length of time.

From the results in animals we have a right to hope that antitoxin injected into human beings will protect them for days, and probably for weeks, absolutely from an attack of diphtheria. A larger amount of antitoxin should cure cases of diphtheria when the lesions are limited to superficial local changes in the pharynx or larynx. We should have less hope for any effect in cases where pneumonia or sepsis had developed, where other micro-organisms played an important rôle, or in cases treated within a few hours of probable death.

IMMUNIZATION AGAINST DIPHTHERIA WITH ANTITOXIN.

By GEORGE A. PECK, M.D.,

RESIDENT PHYSICIAN NEW YORK INFANT ASYLUM.

Instead of entering at once into giving the results obtained from the use of antitoxin as a means of preventing the development of diphtheria, it may, perhaps be best to give a short history of the epidemic of diphtheria that has been holding sway in the Mount Vernon branch of the New York Infant Asylum for the past few months, in order that the conditions under which this remedy has been employed may be better understood and appreciated.

From May, 1892, to February 18, 1894, there was no diphtheria in the asylum—a period of one year and nine months. On the latter date, however, the disease developed in a child received into the asylum but twelve days before from the New York department of the asylum; two weeks later a second case appeared, ten days after this a third, and so on, there being a mild epidemic of nine cases in the May following, the disease then becoming endemic till September 5, 1894, when the present epidemic may be said to have actually begun. During this interval, February to September, a period of but little more than half a year, there were 22 cases of diphtheria and 15 deaths—a mortality of sixty-six per cent. The diagnosis in these cases was made by clinical and macroscopic conditions combined, and could bacteriological examinations have been made in some instances, the number would undoubtedly have been increased, with diminished per cent. of mortality, since there were a number of cases of so-called tonsillitis during this period identical with cases that have since been proven to be true diphtheria.

On September 5, 1894, 2 cases of diphtheria developed, followed by 14 other cases during that month. In October there were 32 cases; in November, 30 cases; in December 31, January 14, February 10, and March 3, giving up to date, 136 cases of diphtheria since September 5, 1894, and 158 cases since February 18, 1894.

During the early part of this epidemic the diagnosis of diphtheria was made from bacteriological examinations by the New York City Board of Health, but later it became necessary to establish a laboratory in the asylum for this particular department of bacteriology, by aid of which, results could be quickly learned and a

more extensive work could be carried on. In the latter part of October, when this was done, bacteriological examinations of the throats of healthy children revealed the fact that Loeffler bacilli were present in so many instances that in order to isolate these cases nearly half of the children of the institution were quarantined. Special attention was paid to these children with regard to checking the progress of the epidemic, but all attempts in this direction were futile.

Through the kindness of Drs. Biggs and Park of the New York City Board of Health, a quantity of Behring's antitoxin No. II. was given for use in immunizing against diphtheria. Accordingly, on December 12th, forty-two children were selected whose throats at that time contained the Loeffler bacilli, and whose ages ranged from one and a half to five years. These children were placed in one of the buildings. To one-half their number (twenty-one) was given the antitoxin, each receiving 150 units. No diphtheria developed among these children, including those who did not receive the antitoxin, for a period of one month, at the end of that time diphtheria developed in a boy four and a half years old, while convalescing from a severe pneumonia, he being one who had received 150 units of antitoxin.

In the meanwhile the epidemic was persisting, cases having developed in other portions of the institution, and the situation was becoming more serious and alarming each day. That the disease should have gained such a wide-spread hold cannot be wondered at when one considers the capacity of the wards, which ranges from twenty to thirty children; and since no building or ward has been exempt from the disease almost every child had repeatedly been exposed to infection, not only from those developing the disease, but also from those healthy children who did not develop diphtheria but whose throats contained the Loeffler bacilli.

Although the first experiment with antitoxin proved nothing, except that the period of immunity it rendered was limited, it was decided to inoculate with antitoxin all the children remaining in the institution who had not had diphtheria as soon as the remedy could be obtained. Accordingly, on January 16th and 17th, two hundred and twenty-four children were inoculated with Behring's antitoxin No. II., the quantity of antitoxin given in each varying from 100 to 200 units, according to age. An examination of the records shows that from January 4 to 14, 1895, twelve cases of diphtheria developed, nine occurring in the last five days of this period. The first case to appear among these children who were inoculated was on February 3d, two and a half weeks after the antitoxin was administered. On February 15th a second case appeared among these children, the interval in this instance being four weeks from inoculation. Preparations were then begun for a second general inoculation, should diphtheria continue to appear among these children. Before these preparations could be completed, however, five more cases had developed, one on February 22d, one on February 24th, two on February 25th, and one on February 27th.

On February 27th and 28th a second general inoculation was given, two hundred and forty-five children receiving the antitoxin, which was a product of the laboratory of the New York City Board of Health. In this instance the dose was increased by 25 units throughout, ranging from 125 to 225 units according to age. From this inoculation there was a period of complete immunity from diphtheria among these children extending over four and a half weeks, a case having developed on March 30th.

It could not be seen that antitoxin had any effect upon the Loeffler bacillus itself, since during the months of January and February the bacilli were found in so many of the children's throats it was necessary to extend the quarantine to nearly every building in the asylum, and, although no bacteriological examination of the throats was made at the time of inoculation, for want of time, yet one may be assured of the presence of the bacilli at that time, since they were found in nearly all at periods either immediately preceding or subsequent to the inoculations. That some of these bacilli were virulent is proven clinically by the cases of true diphtheria occurring in adults and children (the latter being cases of reinfection) during the periods of immunity following the first and second inoculations, and experimentally it has been proven by the New York City Board of Health in the guinea-pig.

The ill effects from the inoculations were limited to a few cases of pronounced urticaria after both general inoculations, and a few needle abscesses after the first, consequent upon haste. Constitutional symptoms with temperature, etc., were almost *nil*.

Nothing more can be said for antitoxin as an immunizing agent against diphtheria, except that the results obtained as stated cannot justly be attributed to coincidence.

RESULTS OF AUTOPSIES ON CASES DYING AFTER TREATMENT WITH DIPHTHERIA ANTITOXIN.

By GEORGE P. BIGGS, M.D.,

NEW YORK.

With so broad a field for discussion as has already been opened by the papers listened to this evening, it would be out of place for me to enter into an exhaustive consideration of the gross and microscopic lesions found after death from diphtheria, especially as the majority of those present are probably interested more in the clinical than in the pathological phases of this disease. I shall therefore confine myself to a brief review of the results of diphtheria autopsies made by myself at the Willard Parker Hospital since my appointment as assistant pathologist to the New York City Board of Health. Lack of time, necessitated by so early a report, has prevented as elaborate an analysis or as critical a study of these cases as could be desired.

Eighteen autopsies have been performed, two in the latter part of February and sixteen in March, this number representing about seventy-five per cent. of the deaths from diphtheria occurring during this time. As thorough bacteriological examinations have been made in but a small proportion of cases, my report will be only of the pathological findings, particularly those having important bearing on the clinical course of the disease. In each case gross lesions have been recorded by dictation during the performance of the autopsy, and portions of the various organs have been subsequently studied in the fresh state by making frozen sections, and later in hardened sections from Müller's fluid and alcohol.

We may class the lesions found under four heads, viz.:

I. Local lesions in the nares, pharynx, tonsils, larynx, and trachea.

II. Lesions constantly present in varying degree in the internal organs.

III. Complicating lesions not invariably present.

IV. Lesions of antecedent disease.

1. **Local Lesions.**—In 6 of the 18 cases no membrane whatever was found. Five of these had been cases of laryngeal diphtheria, and slight ulceration of the larynx, chiefly of the vocal cords, still persisted in three of them.

Membrane, when present, was comparatively thin, in most cases 1 to 2 mm. in thickness, and as a rule loosely attached to the underlying tissues except in the larynx, where it was usually quite adherent over the vocal cords at least. In two instances, however, tonsillar membrane was found very adherent, but these were in patients who received antitoxin for the first time on the sixth

and eighth days of the disease, and did not respond to treatment.

Clinically, 13 of the patients were distinctly croupy, and in one instance the disease was exclusively laryngeal in character. The autopsy records show 2 additional cases in which the larynx was involved, making a total of 15 out of 18 cases in which the larynx was invaded.

Of the 12 cases in which membrane was found at autopsy, in only 2 was the larynx free from involvement. One of these cases was three years of age, was admitted to the hospital on the seventh day of the disease, and died two days later. The autopsy showed an acute exudative nephritis and miliary tuberculosis. The second case was a child three and a half years of age, who was admitted on the fourth day in a very septic condition, with extensive gangrenous process in the throat, and who died within a few hours. Eight of the ten laryngeal cases had required intubation, but only one tracheotomy. In four the membrane was limited to the larynx, or larynx and upper trachea, and in six it covered the pharynx and tonsils also. Deep necrosis of the tonsils was found in two cases and both of these were clinically decidedly septic. Distinct enlargement of the cervical lymphatic glands usually existed, but was at times only slight.

II. Lesions Constantly Present in Other Organs.—The lesions constantly found in the internal organs were chiefly parenchymatous and fatty degenerations of the heart, liver, and kidneys. These changes have been more or less prominent features in all the cases, though the degree of degeneration has varied within wide limits. In a general way it may be stated that they were more advanced the later the cases came under treatment. Those treated early showed a mild degree of degeneration, while in three cases first receiving antitoxin on the seventh, seventh, and eighth days respectively, there was extreme fatty degeneration.

These facts point clearly to a marked influence exerted by antitoxin, when administered early, in checking and preventing these destructive changes.

III. Complicating Lesions not Invariably Found.—These were most frequent in the lungs. Bronchitis of greater or less severity existed in all cases, twelve being characterized by abundant purulent secretion with intense inflammation of the bronchial and peri-bronchial structures, and six by muco-purulent secretion, with inflammation of the bronchial mucous membrane only. Distinct membrane was found in the bronchi in only one case.

Pneumonia in some form was found at all but two autopsies, the consolidation being lobar in one instance and broncho- or lobular in the remaining fifteen. The lobar consolidation developed several days after complete recovery from diphtheria, and was the sole cause of death. Excluding this case, the percentage of broncho- or lobular pneumonias was eighty-eight, a proportion much higher than that usually given. This fact would tend to show that the improvement in mortality under the antitoxin treatment of diphtheria is due to its influence on cases not complicated by broncho-pneumonia.

Eleven of the broncho- or lobular pneumonias may be classified as extensive (involving one-third to one-half of each lower lobe and usually smaller portions of the middle and upper lobes), two as moderate in extent, and two as slight.

Acute fibrinous pleuritis complicated the case of lobar pneumonia and one case of extensive broncho-pneumonia. Thrombi were found in the small pulmonary vessels but once. The spleen was seldom enlarged or softened, but usually congested.

In two cases the kidneys, in addition to advanced parenchymatous degeneration, presented the typical lesions of acute exudative nephritis. In each instance the patient did not receive antitoxin until the seventh day of the disease, and death occurred two days later.

IV. Lesions of Antecedent Disease.—Lesions of antecedent disease which could be looked upon as important factors in explaining the fatal termination have been chiefly of a tubercular character. General miliary tuberculosis existed in two of the cases; tuberculosis of the lungs, bronchial glands, and liver, in one case; and of the lungs and bronchial glands in two others. Syphilitic cirrhosis of the liver was very marked in one instance and slight in another.

The unfavorable conditions under which treatment was begun in many of these cases may be judged from the following facts:

1. Age.—The average age of the patients was two and a half years, the oldest being five and a quarter years, and the youngest eight months. Eight were two years old or younger, 6 were between two and three years old, 2 between three and four years, 1 five years, and 1 five and a quarter years.

2. Duration of the Disease Prior to Administration of Antitoxin.—This averaged 4.4 days; 2 receiving treatment on the second day, 4 on the third, 5 on the fourth, 2 on the fifth, 2 on the sixth, 2 on the seventh, and 1 on the eighth day.

3. Location of Membrane.—As already stated, 15 were laryngeal cases; 10 requiring intubation and 1 tracheotomy.

Taking an average of all cases, death occurred seventeen days from the beginning of the disease. Excluding three which terminated fatally within twenty-four hours after admission to the hospital, the average period is extended to nineteen days from the onset of the disease.

In order to ascertain the number of apparent failures of antitoxin in the treatment of these patients, we must first exclude from the series two cases in which death was not the result of diphtheria or of any of its direct complications. One of these died of typical lobar pneumonia, which developed several days after complete recovery from diphtheria, and the other of marasmus and prolapse of the rectum three weeks after disappearance of Klebs-Loeffler bacilli from the throat. No membrane was found in either case at autopsy.

Of the sixteen cases in which the immediate cause of death was diphtheria or some of its complications, the following should, for obvious reasons, be excluded from those in which the antitoxin treatment may be considered to have failed:

1. Two cases complicated by general miliary tuberculosis, which it is fair to say would have been hopeless under any method of treatment. These patients first received antitoxin on the fourth and seventh days respectively.

2. One in which no antitoxin was given, owing to the fact that a second and fatal attack of diphtheria developed so insidiously as not to be recognized, when the patient had almost recovered from a severe broncho-pneumonia. This had complicated an attack of diphtheria occurring four weeks before.

3. Two cases, treated on the sixth day, with a serum of entirely inadequate strength.

4. Two admitted to the hospital on the fourth day of the disease, in a state of profound sepsis, and dying, one a few hours after admission and the other within twenty-four hours.

Among the 9 cases still left for consideration there are 3 in which no diphtheritic membrane was found at autopsy. Death was accounted for in 2 of these (both treated on the fourth day) by extensive broncho-pneumonia, and in the third by extensive fatty degeneration of the heart, acute exudative nephritis, and the septic condition of the patient when admitted on the seventh day of the disease.

There remain 6 cases, all with laryngeal involvement and requiring intubation, and all complicated by more or less broncho-pneumonia. In 3 of these, first treated on the third, fourth, and eighth days respectively, broncho-pneumonia was most extensive, and

amply explained the fatal termination. In the three cases remaining the broncho-pneumonia found was not sufficiently extensive to of itself explain death. The following facts, derived from the clinical histories, have a bearing on the fatal result. One was a child two and a half years of age, admitted after three days' sickness, with marked obstruction requiring immediate intubation and a little later tracheotomy. Death occurred two days later. The second case, one year of age, was admitted five days after the onset of the disease, and died in two days. The third case was aged but eight months, was admitted after five days' sickness, and died within twenty-four hours.

Although the number of autopsies reported is comparatively small, the writer feels justified in making the following deductions:

1. That antitoxin has a decided influence in loosening diphtheritic membrane, even in cases resulting fatally.

2. That it has comparatively little influence on the cases already complicated by broncho-pneumonia.

3. That it has a marked influence, when administered early, in preventing and checking parenchymatous and fatty degenerations.

5 West Fifty-eighth Street.

Clinical Department.

AN ANENCEPHALOUS MONSTER.

By R. H. PHILLIMORE, M.D.,

cookshire, p. q., canada.

At 8 o'clock in the morning I was recently summoned to attend the confinement of Mrs. ——. The patient was eighteen years of age, very anæmic, and a primipara. I found her sitting up and suffering from occasionally severe pains. Labor had commenced forty-eight hours before. An external examination revealed a uterus enormously distended—so much so that the women in attendance, much to the anguish of the husband, were firm in their conviction that triplets were at least to be expected. By palpation nothing definite in regard to the presentation could be determined, while the fœtal heart-sounds were entirely absent.

Upon making a digital examination, I found the os partially dilated and the bag of waters protruding. The membranes were extremely tough and resisted several attempts at rupture. Eventually, however, this was accomplished, and an immense quantity of amnial fluid gushed forth—literally deluging the bed, and pouring down onto the floor. Shortly after I made another digital examination, and found a hard body presenting, almost flat to the touch, while close at hand was evidently the right ear of the fœtus. The shoulder, to my surprise, appeared to be almost continuous with the head. Pains now occurred at regular intervals; but owing, as I rightly conjectured, to some strange abnormality in the formation of the head, progress was extremely slow. At noon birth was accomplished, and a female monstrosity was delivered. Fortunately, it died after giving vent to a few spasmodic attempts at breathing.

The formation of the fœtus was, I think, sufficiently curious to justify me in placing before my readers a photograph of the deformity, with a description illustrative of its peculiar features. Its weight was three pounds. The head is small and placed almost directly upon the shoulders, being separated only by a short, stumpy neck. The eyeballs are extremely prominent, the pupils opaque, and altogether bearing a strong resemblance to those of a frog. The nose is flat, while the tongue slightly protrudes, being evidently too large for the mouth to accommodate. The hair is very dark; and in its curious formation gives the monster an appearance almost bordering upon the ludicrous. From the occipital protuberance, running downward for a distance of three inches, is what, at first sight, appears to be a deep gash. It resembles a clean, straight cut, as though it had been made with a sharp knife; the lips of the wound are everted, disclosing an interval of one inch and three-quarters, apparently filled in by a raw-

looking, granulating surface. At the summit of the apparent wound is a slit running transversely and of considerable depth, possibly communicating with the cranial cavity; above is a kind of sac, consisting of a tough membrane, corrugated and movable. The whole is bridged over by a bluish skin, continuous with the integument of the body, which is remarkable for its unique pink color. In other respects the trunk and extremities are perfectly formed.

I have not, at present, been able to elicit any instructive information respecting the history of either father or mother. Whether, however, the red area on the back of the fœtus, to which I have alluded, is due to some psychical condition on the part of the mother during pregnancy, or to some error in development in early fœtal life, I must leave to the speculation of my readers. The question, however, of the development and growth of monstrosities, and the curious so-called "maternal impressions," with which children are occasionally born, are now so imperfectly understood, that any additional information, gathered either from personal observation or from the study of embryology, must necessarily be greeted with a warm welcome on the part of the medical profession generally.

EPISTAXIS AND PREGNANCY; REPORT OF A FATAL CASE.

By THOMAS HUBBARD, M.D.,

toledo, o.

On January 10, 1894, I saw, in consultation with Dr. G. A. Hollister, Mrs. C——, aged forty, mother of ten children. She was of strong, vigorous habit, and usually very calm and self-controlled. At this time she was within a week of the anticipated period of confinement. About one year, and again five months, previous, she had had very severe epistaxis, having bled until nearly in collapse. She rallied very slowly from the last attack, being then about four months pregnant, and never recovered her equanimity. She was in constant dread of recurrence, and repeatedly declared that she never could survive another attack.

We found her on the date above noted bleeding profusely, and in a condition of intense apprehension and dread. The hemorrhage was unusually severe, and even after the removal of all clots with salt water and securing good illumination, it was very difficult to locate the bleeding point. It was finally approximately determined to be from the septum, near the anterior end of the middle turbinated process. A ten per cent. solution of cocaine was applied on a cotton probe, us-

ing firm pressure. After holding this in place for about five minutes, the hemorrhage was stopped, but of course only temporarily. In fact, the hemorrhage which will surely supervene after cocaine has been used as a temporary hemostatic is nearly always more severe than before.

It is my usual practice to continuously inspect the membrane after thus applying cocaine, watching for the bright pink bleb which will appear in sharp contrast to the surrounding area made anæmic through the action of cocaine, aided by the firm pressure with the probe. This physiological action of cocaine is more transient in effect upon the ruptured artery, as is evidenced by the early appearance of the pink spot, usually about the size of a pin-head. In this case, the location of the source of hemorrhage was thus verified after about ten minutes continuous inspection. A small bead of chromic acid, fused on a copper probe, was applied to the spot and contiguous area, producing a firm eschar.

It was observed that she had atrophic rhinitis, and there were many areas of superficially eroded mucous membrane. An alkaline antiseptic douche kept the nose fairly free from incrustations, and she had no more hemorrhage until nine days after confinement, January 27th. She had been delivered of a healthy child in normal labor.

On the morning of this day she had walked about the house, and about noon as she sat in her chair epistaxis came on suddenly. The amount of blood lost was not great, but it seemed to shock her profoundly. All preparations for the anticipated demise had been made when we arrived, and it was impossible to revive her courage. The bleeding point was thoroughly cauterized, after considerable delay in checking the hemorrhage sufficient for the application of the escharotic, and she was put to bed in very comfortable general condition.

The urine was examined and found normal, and there was no other constitutional disorder suggested. The lochia were natural, but the milk was scanty.

No immediate untoward symptoms followed. There was not even the usual amount of frontal and intranasal pain following cauterization. The antiseptic douche was used three or four times daily. She continued to show great depression and remained in bed in an apathetic condition.

I had discontinued visits, when on February 2d the husband requested me to see her, as the eschar had detached and they feared hemorrhage. Examination showed the whole mucosa more than usually dry and feverish. There were no symptoms indicative of local sepsis, neither was there pain, nor odor from the detached incrusta. I had been summoned solely because they feared hemorrhage from detachment of eschar. There had been no chill nor symptom of serious systemic disturbance. She had complained somewhat of lumbar and post-cervical pains, but for the most part seemed comfortable. Her temperature was found to be above 103° F. The day following it was 104° F. The lochia and milk were suppressed; lumbar pains continued, and a few days later intense pain in one ankle and one right thumb-joint supervened.

The condition of the nose remained the same to the end. There were no symptoms except such as were referable to a high temperature affecting a previously dry and scabby membrane. The antiseptic nasal douche was used faithfully, hydrogen peroxide having been added to the alkaline solution several times daily, and a vaginal wash was employed, there being slight odor from the vagina. The general treatment included the administration of ergot, quinine, strychnine, and salol.

She died in about ten days, the abscesses of the ankle and thumb being the only evidences of metastasis. The temperature ranged very high, often reaching 106° F. The mind was clear to the last hour, but she was throughout the whole sickness rather inclined to drowsiness. During the last day there was considerable abdominal tenderness and diarrhœa.

The pathology of this unfortunate case is rather obscure. It seems to me that the epistaxis and consequent shock was the most prominent factor in disturbing the normal physiological processes of the puerperium, which resulted in toxæmia or pyæmia. The sequence of pathological conditions was probably as follows: She was still in the puerperal state; mental shock induced fever; the uterine and vaginal, together with the already atrophic and unhealthy nasal mucous membranes were thus the source of sapræmia, which condition in turn increased the fever. This gradually merged into a condition of fatal toxæmia. Whether or not such a case could properly be called pyæmia could be determined only by the bacteriologist.

The occurrence of epistaxis during pregnancy is not rare. I have seen and treated five such cases in which the hemorrhage was more or less severe. They were all between the fourth and seventh month. In no case was there any disturbance other than a normal pregnancy, and in only one (the case narrated in detail) was there a history of previous severe epistaxis. In all of the cases a ruptured septal artery was located, and one cauterization sufficed to cure in four of them.

There is a general opinion expressed in the literature of the subject, that hemorrhages of this class are of the same nature as vicarious menstruation. That the nasal mucous membrane may be subject to this condition cannot be controverted, but in a majority of cases epistaxis is determined by other factors. The condition of pregnancy is so often accompanied by vasomotor disturbances of the mucous membrane, such as: nasal hydrorrhœa, or vaso-motor rhinitis, and acute pharyngeal pyperæmia, not to mention gastric disturbances, that it is not difficult to account for one of the predisposing causes of epistaxis. A determining cause is a weakened or eroded blood-vessel. As stated, this is situated usually in the anterior third of the septum.

As a rule, the rupture of an artery within the substance of the septum occurs because of the gradual wearing away of the supporting cartilaginous tissue in contact with the convex surface of the arterial loop. The impingement of the arterial current is greatest at this point, and the poorly nourished cartilage wastes before the pressure. The loop thus gradually loses support on one side, and eventually the weakened wall gives way. Of course, any form of superficial necrosis of mucous membrane or atrophy may aid in bringing about the same result. In this case the recurrence of hemorrhage was doubtless caused by the tendency to superficial necrosis.

In regard to treatment, we would simply impress the fact that the earlier cases like the one narrated are treated, the less danger. The nearer to the period of confinement, the risks from loss of blood, mental shock, and septic complications are decidedly augmented. Cauterization, after the manner detailed, is the way to deal with such cases. The post-nasal tampon materially increases the danger from sepsis, and should be avoided if possible.

Note.—In the discussion of this paper before the Toledo Medical Association, Dr. H. Hathaway advocated the administration of strychnine in heroic doses, $\frac{1}{60}$ to $\frac{1}{30}$ gr. hypodermatically, every two hours, in cases of hemorrhage during the puerperium. This treatment would have been adapted to this case, as the general nervous depression was pronounced.

It may further be stated that the atrophic rhinitis was in this case unilateral, being found on the side presenting the concavity of the deviated septum. There was not the fetor of advanced ozæna, but the whole surface of the septum was inclined to formation of incrusta, and slight excoriations consequent upon their detachment.

AN OSTEO-SARCOMA IN THE NOSE OF AN OX.

By JONATHAN WRIGHT, M.D.,

BROOKLYN, N. Y.

During a few hours spent in the country I heard one of my farmer friends say that he had sent an ox to the slaughter-house in New York that day who could not breathe through his nose. Considering that this domestic animal was legitimate game for the rhinologist, I sent the next day to the slaughter-house and succeeded in securing the whole head, and exhibited it that night, with its contents, before the Laryngological Section of the Academy of Medicine. The nasal cavities were filled by an irregularly rounded tumor, which was about 24 ctm. (9 inches) in its longest diameter and about 12.5 ctm. (5 inches) in its shortest diameter. It was most firmly attached to, and seemed to have grown from the internal face of the external wall of the left antrum about 10 ctm. below the orbit. It had grown in every direction—upward, far enough to absorb the lower and internal walls of the orbit, and this had evidently during life produced some exophthalmus. It had caused absorption of a large part of the intranasal structures, especially on the left side. It had made its way across the left nasal fossa through the septum and into the right antrum, part of which it filled, the left antrum being almost entirely obliterated by the growth. About three-fourths of the mass was made up of cancellous bone-tissue, some of which, however, was much more dense than ordinary cancellous tissue. The soft parts and external surface of the tumor were irregularly lobular, and there seemed to be a capsule which in places was adherent to the bony walls of the nasal cavities. There were one or two cysts which contained semi-gelatinous light-colored glairy fluid.

Several pieces were taken from various portions of the soft parts of the tumor and examined microscopically. It was found to be made up of fibrous tissue densely infiltrated with small, spindle-shaped cells having for their support a stroma derived from the fibrous bands which traversed the mass more abundantly in some places than others. Here and there were areas of œdema in which the branching cells of the new connective tissue could be seen. The surface was covered with cylindrical epithelium. There were very few blood-vessels; only a few of the nuclei of the spindle cells were in process of division. Evidently it was, then, an osteo-fibro-sarcoma with small spindle cells and apparently of moderately slow growth.

It is the custom in the section of country whence this ox came for the driver, when he desires to reprove or stimulate his beast, to whack him over the nose with any convenient object, varying, according to the benevolent instincts of the man and the exasperating obstinacy of the ox, from a leather leash to a hickory club. From the situation of the origin of this growth and its nature it is fair to presume that it resulted from the severer form of some such disciplinary violence.

ICE IN THE TREATMENT OF PNEUMONIA.

By CARL ENGEL, M.D.,

MINDEN, IOWA.

On February 2, 1894, I was called in haste to see a two-year-old girl, who had been treated by another physician for some time. I found the child nearly moribund. Temperature, 107° F.; pulse not countable; cheeks flushed; thumbs flexed upon the palms of the hands; head continually rolling from side to side. Examination revealed double pneumonia and leptomeningitis. The case was apparently hopeless. I prescribed a diaphoretic consisting of aconite, ipecac, liquor ammonia, acetatis and spiritus ætheris nitrosi, and also left some asafœtida powders and eight doses of potass. bromide of three grains each.

No improvement taking place, on February 5th I ordered ice to be applied to the head and to be kept on also part of the night. Two ice-bags were employed, one on each side. On the following day I directed that ice be applied also to the chest. I had to deal with a great deal of prejudice, and when the father of the sick child procured the ice, people denounced the procedure as foolish and dangerous. Small doses of strychnine were also ordered. On February 7th, the temperature was lower. Directions were given to keep the ice continually on the head and chest night and day. On the day following this the temperature was normal.

The application of ice was continued for four days longer. It was then discontinued and digitalis was ordered.

Laryngitis or rather laryngeal paralysis appeared, for which I ordered German creosote for inhalation with steam. There had been a severe cough, but that was relieved by muriate of ammonia and terpin. The diet consisted throughout of milk previously boiled, and at times with the addition of aquæ calcis and beef-tea, also occasionally brandy diluted with water.

A CASE OF TRIPLETS.

Dr. John M. Denison, of Blatchford, O., writes: "On January 25th Mrs. Moses Powell, of this place, gave birth to triplets, all girls, weighing 5¼, 5, and 5 pounds each. First born 7.15 P.M., breech first. Second, 10.50 P.M., head and hands. Third, 11.05 P.M., normal. Mother is a brunette of twenty-six years; has had two children prior to these. Mother and children doing nicely to date, and give promise of a continued healthy condition. I merely mention this, thinking, perhaps, the fact might be worth reporting."

A CASE OF TRANSPOSITION OF HEART, LIVER, AND SPLEEN.

By GEORGE S. DIXON, M.D.,

NEW YORK.

S. C——, aged sixteen, peddler's boy, born in the United States of Russian parents. Nothing unusual in the family history. Father living, in good health. Mother died of "abscess during confinement."

Patient has had but one serious illness, pneumonia. Has had "chills and fever," but none of the children's diseases except measles. He is bright, intelligent, and well formed. He presented himself at the Demilt Dispensary last November for the relief of "stick pains," as he termed them, at the lower border of ribs on left side. A snap diagnosis of dry pleurisy was made, but the facts revealed by the physical examination, which was immediately made by the writer, did not confirm it. The liver was found to begin one and one-fourth inch below the left nipple, was somewhat larger than normal, and occupied the space to which the pain was referred. There was slight rise in temperature, no jaundice or other symptom indicating anything more than a mild attack of perihepatitis. Patient stated that he had these attacks about twice a year. At the same time the heart was found transposed, the apex-beat being in the sixth intercostal space one and one-fourth inch inside the right nipple. The aortic second sound was best heard in the third intercostal space to the left of the sternum. Reduplication of the first sound was present, also a soft blowing murmur with this sound not transmitted. There was slight hypertrophy. No subjective symptoms whatever relating to heart. The spleen was found on the right side of about normal size and in relatively good position.

This case was shown before the Pædiatric Section of the Academy of Medicine, February 14, 1895, by Dr. Henry D. Chapin, and the transpositions verified by Dr. A. Jacobi.

CEREBRAL HEMORRHAGE AS A SEQUEL TO ENTEROCOLITIS.[1]

By F. P. EMERSON, M.D.,

ROXBURY, MASS.

The following case is of interest not only because of its rarity but as a contribution to the study of scurvy, which, it is being recognized, may follow as the result of an exclusive feeding of sterilized milk as well as from the various infant-foods which so far have failed to be an ideal substitute for breast-milk.

Mrs. C—— consulted me, August 1st, for her baby of five months, who was having five or six loose greenish stools streaked with mucus and for the first time with a little blood. Child had been for six weeks on sterilized milk, and during most of that time had suffered more or less from diarrhœa. During the first four weeks he was under the professional care of a regular practitioner, who ordered the milk discontinued, to be followed by rice-water for twenty-four hours and antidiarrhœal mixtures, and then a gradual resumption of the sterile milk, which was carefully prepared in an Arnold sterilizer, with definite directions as to the proportions of milk, cream, sugar of milk, lime-water, etc. After six weeks he came under my care, and at this time he was five months old, of well-to-do parents. Weighed at birth 9½ pounds, and at this time 11 pounds. He was pale, with skin somewhat flabby, took his milk voraciously and in large quantities, and gave one the impression of malassimilation. The whole quantity of nourishment was taken rapidly and every two hours. I directed that the time be extended and that he be required to eat slowly and in his mother's arms, also that the milk be only Pasteurized, as the cream seemed emulsified. As there was no improvement I changed to peptonized milk with small doses of the mild chloride and a mixture of bismuth and salol.

August 3d.—The third day after coming under my observation the temperature in the morning was 100° F., and afternoon 101½° F. Stools, twelve to fifteen in twenty-four hours. Fontanels not markedly depressed.

August 4th.—Temperature the same, and number of stools, but some were a mere staining of his tidies. Mouth and lips red, and mother thought his back a little crooked: but I could not detect any abnormality.

August 5th.—Conditions the same, but eats more naturally, *i.e.*, less frequently and more slowly. Has been in the hammock all day.

August 6th.—Temperature 100° F. at 9 A.M. Seven stools during the night, but only two of any amount. Looks brighter. As there was a little straining, with some irritation of the rectum, I ordered an enema of $AgNO_3$. Up to this point the child seemed much better; was out of doors in the hammock all day; ate more naturally and looked so well that his mother considered him out of danger. But there was an element in his disorder which I had not recognized, and which the unhappy sequel, I think, proves to have been scorbutis, as on the 7th he had only five stools, which were better formed, and the temperature rose to 101° F. in the morning and 102½° F. in the afternoon, and thinking it was owing to his food, I again changed to the Walker-Gordon Lab. product; but subsequent events proved it to be the forerunner of a hemiplegia which occurred at 12.20 of the 8th, when I was suddenly called and found facies pale; respiration shallow and irregular: eyes fixed; pupils equal; pulse weak; extremities warm. After an hour the head was turned to one side (right side) and rigid. Left lower limb flaccid. Left arm rigid and could not be extended, remaining semiflexed. Child apathetic. Reflexes intact. Right arm in motion, and when first seen convulsions seemed imminent. At 4 P.M. temperature in R. A. 100° F.; L. A. 99⅘° F. Two hours and a half after initial attack commenced to move entire left side, but grasp not as strong, and at five acted hungry and took his bottle. Still apathetic, and has made an audible sound only twice. This attack was followed by a second, and the child died at 3.45 A.M., on the eighth day after it came under my care.

I find the literature on hemiplegia as a sequel to enterocolitis, exceedingly meagre. Keating says in eighty-three cases of hemiplegia one was due to enterocolitis, but taking the element of scurvy into consideration, we would expect a hemorrhagic effusion into any of the closed cavities as a result of malnutrition, and a consequent weakening of the vascular walls. Two such cases were reported during the summer of 1894 in the brain. This I believe to have been the case here, and that the child's milk for him was impaired in its digestibility by sterilization, whether by converting the soluble proteids into insoluble, by destroying the ferment, emulsifying the fat, or by rendering the casein indigestible, I do not know, but I believe a complex fluid as unstable as milk cannot be subjected to continuous heat without detriment to its nutritive properties, except as a temporary measure.

SKIN GRAFTING ON THE BALL OF THE EYE FOR SYMBLEPHARON.[1]

By TALBOT R. CHAMBERS, M.D.,

JERSEY CITY.

CONSULTING OPHTHALMOLOGIST TO ORANGE MEMORIAL HOSPITAL; OPHTHALMOLOGIST TO THE CITY HOSPITAL, JERSEY CITY.

Well knowing that the general practitioner usually excludes diseases of the eye from his field of work, I venture to present a case because of some unusual features of interest.

Thomas Fitzsimmons, of South Orange, aged nineteen, a mason's apprentice, while unloading a wagon, allowed a barrel of mortar to fall, and some of the flying lime entered his left eye. He came under my care in the Orange Memorial Hospital, and I saw him shortly after the accident. The burn was quite deep in the mucous membrane behind the lower lid, and superficially upon the cornea.

The treatment in the days immediately following the accident was directed to the one purpose of keeping the cicatrix which was to follow as small as possible. Notwithstanding, there was quite a band formed between lid and ball, causing much pain and discomfort.

It is to two points your attention is particularly called. The idiosyncrasy against cocaine; and the fact that skin grafted on to the ball, not upon the lid, but upon the eyeball, cured the symblepharon.

I have failed to find any record of such procedure before. It was done in this case because it seemed to promise more than the transient relief which would be afforded by grafting upon the lid. And, indeed, now that it has succeeded, I may say it was really more easily and effectively done. From the hospital record-book it is found he entered the hospital, November 24, 1892; left December 8th, remaining two weeks. Re-entered December 10th; left December 19th, remaining nine days. Re-entered December 28th; left March 6, 1893, remaining two and one-half months. Re-entered March 7th; left March 22d, remaining two weeks and one day. Re-entered July 22d; left July 31st, remaining one week. Re-entered September 18th; left September 29th, remaining ten days. Re-entered October 18th; left October 25th, remaining one week.

He was thus during the year following the accident in the hospital seven times for and on account of this eye. On all of these occasions except the first he complained of pain on moving the eye upward. Cica-

[1] Read before the Hudson County Medical Society, March 5, 1895.

tricial bands were cut and various plastic operations were done to relieve the pterygii forming and reforming. In October, 1893, he was practically blind in this eye, besides having more or less constant pain. The lachrymation was a most troublesome feature, and in fact he was altogether miserable.

On October 18th, an elongated ellipsoid piece of skin was grafted from the adjacent temple upon the ball of the eye. The ball was denuded of all cicatricial tissue, and this flap of skin was twisted around its pedicle at the external canthus and sewed to the ball, it being carried well down into the sulcus between lid and ball. The pedicle remained between the lids for four days without giving any annoyance when it was severed; and now, eighteen months since the operation, he has not lost one minute's sleep nor one day's work on account of the eye. He presents a fairly good-looking eye, has a vision of $\frac{1}{5}\frac{0}{0}$, and above all, retains his eye and is comfortable. At one time it seemed impossible to save the eye at all.

The very strange action of cocaine instilled into the eye is certainly remarkable. On the first three occasions when operations were performed, a sufficient amount of cocaine solution was dropped between the lids to produce anæsthesia. It was followed in a couple of hours by a maniacal condition, in which it was necessary to place a camesole about him, and for three days and nights keep him under restraint, tied to his bed. On one occasion this was accompanied by a rash over the whole body very closely simulating typhus fever. His idiosyncrasy against cocaine was such that general etherization was always afterward preferably employed.

PLACENTA PRÆVIA—DEATH FROM SHOCK AFTER DELIVERY.

By A. C. HARRISON, M.D.,

MEYERSDALE, PA.

On February 3d I was called in consultation with Dr. O. G. Getty, of Meyersdale, to see Mrs. ——, a multipara, aged forty-two, and in the eighth month of pregnancy. She had had repeated hemorrhages during the preceding three months, and Dr. Getty had made a diagnosis of placenta prævia. The pulse was rapid and weak, patient nervous and sighing. There was an occasional effort at uterine contraction and intermittent hemorrhage. Examination showed a patulous os, admitting one finger easily, with placenta prævia centralis, separated from the margins of the cervix for an inch or more. The general condition seemed fairly good, though the patient showed plainly the effects of acute anæmia. Immediate delivery was advised and accepted.

The necessary arrangements were hastily made and the patient put to sleep with chloroform. Under its influence the pulse almost ceased. Ether was substituted and the pulse improved markedly. Delivery was accomplished in the usual way; placenta separated as far as the finger could reach, as dilated to admit the hand, placenta perforated, pedalic version and the half breach brought down.

Extraction was as slow as deemed advisable and the placenta delivered immediately after. The whole procedure occupied about thirty minutes. A hypodermic of 30 ℥. of ergot was given and the uterus contracted firmly, hemorrhage ceasing entirely. The pulse was weak, but the general condition did not seem specially alarming. For the weak heart's action one-thirtieth grain of sulphate of strychnia was given hypodermically and five or six hypodermics of whiskey. She was surrounded with hot bottles and one-half gallon of warm water injected into the rectum. The uterus remained firmly contracted and there was no further hemorrhage, but in spite of all efforts she rapidly sank and died of shock in about thirty minutes after delivery.

The patient became conscious in a few minutes after the anæsthetic was withdrawn, sufficiently so to ask for water, which was given warm. There were no lacerations, and bleeding was not great at any time after the operation was begun.

The fact that the heart's action became very bad under chloroform and improved very markedly under ether is a point worthy of note.

Progress of Medical Science.

Pancreatic Diabetes.—The subject of the pathogeny of diabetes was brought prominently before the recent meeting of the French Congress of Medicine at Lyons, and was discussed by Lancereaux, Lépine, Glenard, Comby, Teissier, Charrin, Renault, and others. We shall here take up but one aspect of the question and state the principal facts on which the existence of pancreatic diabetes is affirmed; these facts are now numerous, and are constantly increasing. (*The Boston Medical and Surgical Journal.*) In 1877 Lancereaux reported to the Academy of Medicine, with the morbid specimens, two interesting cases of "grave diabetes," dependent (as he believed) on destructive lesions of the pancreas. In 1879 appeared the inaugural thesis of Lapierre on diabetes, caused by alterations of the pancreas. The disease, as he describes it, begins suddenly, and manifests itself by intense thirst and hunger, then by abundant polyuria with sugar oscillating between three hundred and six hundred grammes per day, and rapid emaciation, with loss of all the forces, and finally complications (broncho-pneumonia, diabetic coma, phthisis) that carry the patient off. The same writer published a subsequent memoir founded on twenty well-observed cases; in fourteen of these there was atrophy of the pancreas more or less advanced. In some the disease was due to calculous obstruction of the duct, in others to chronic disease followed by atrophy of the organ, and in still others by sclerosis. These observations received powerful confirmation by the experimental results of Mehring and Minkowski, who extirpated the pancreas in dogs. They found that diabetes begins a short time after extirpation and persists till the death of the animal. "In addition to the glycosuria there are polyuria, great thirst, hunger, and rapid emaciation." In one dog, which had fasted forty-eight hours, the urine contained from five to six per cent. of sugar, while another dog, weighing sixteen pounds, fed on an exclusive meat diet, eliminated daily almost one litre of urine with six to eight per cent. of sugar. The urine also contained acetone. No glycogen was found in any of the organs after death, even in animals that had been dead four weeks or more. It was said there was no injury to the solar plexus by the operation, so that the diabetes could not be referred to nervous influence. These investigators noticed that whenever there was left any fragment of the pancreatic tissue in the abdomen, glycosuria did not develop. The total ablation of the pancreas produces a permanent diabetes, and this comes on immediately and attains its maximum in two or three days. Dominicis, an Italian physiologist, made subsequently a similar series of experiments, though without absolutely identical results; in a few of his animals (one-third of the cases), the diabetes failed to appear after total extirpation of the pancreas, and where the disease did appear, it was not till twenty or thirty hours after the operation. Redmond, of Metz, in 1889 and 1890, published some experiments made with Marinisco and Chaput, as the result of which they conclude that total destruction of the pancreas generally produces permanent diabetes, and that even partial ablation of this organ is sometimes followed by the same effect. Hedon excised the pancreas in twenty-two dogs, and in each case diabetic urine was

passed the day after and persisted until death, with all the characteristic symptoms of saccharine diabetes. When injections of paraffine were made into the pancreatic duct, destroying the digestive function of the gland, diabetes did not supervene. Thiroloix succeeded by a novel method in completely destroying the pancreas, and yet in keeping his dogs alive a long time. By injecting asphaltum into the pancreatic duct, he caused sclerosis of the organ, which became shrunken to a hard, firm cord, deprived of all gland-cells, yet under these conditions glycosuria did not appear. In other cases he removed a portion of the pancreas, after which he obtained symptoms of intense glycosuria. In another series he removed the whole of the pancreas and obtained a lasting diabetes. On autopsy lesions of the solar plexus were noted. His conclusion is that oblation of the pancreas acts reflexly, by its influence on the nervous system. In other words, "pancreatic diabetes may be regarded as a particular form of nervous diabetes." This does not differ from the old theory of Klebs, which regards diabetes as an expression of lesions of the solar plexus. This is the view of the pathogeny of "lean" (grave) diabetes held by Mathieu in the *Traité de Médicine*. Lépine, who was co-referee at the recent Lyons Congress, has recorded forty cases of removal of the pancreas in dogs. After complete removal he has always noted the appearance of sugar in the urine within eight hours, and the diabetes is permanent. He believes that the blood has the power of constantly destroying glucose by the action of a ferment made in the pancreas (glycolytic ferment); this ferment is diminished in diseases of the pancreas and wanting when that gland is destroyed. Lépine adduces experiments which he thinks sustain this view. It is interesting in this connection to note that Thiroloix, in considering the results of pancreatic grafting, an ingenious device practised by Minkowski, Hedon, and himself (whereby the pancreas in dogs is brought out of the abdominal cavity and grafted into the muscles of the external walls), has modified his former theory, and has adopted Lépine's conclusion, "that the pancreas produces the principal glycolytic ferment which destroys glucose in the blood" and thus prevents its reaching the urine. De Renzi and Reale, in their numerous experiments, have caused diabetes in .75 per cent. of the animals on which they produced entire extirpation of the pancreas. They also claim to have caused glycosuria by extirpating the salivary glands (parotid and submaxillary). Minkowski, in reviewing their work, says that diabetes never fails to appear after complete removal of the pancreas if the animals live long enough after the operation. This statement is founded on fifty-five experiments made on dogs. Three times only did the sugar fail to appear in the urine; but the dogs succumbed during the first twenty-four hours. As to glycosuria after incomplete extirpation, he admits its existence, though in general it is slight; in one case, however, there was serious diabetes, though the fragment of pancreas left was fairly large. He regards glycosuria following extirpation of the salivary glands as only temporary. Lépine, in his communication to the recent Congress, October 29, 1894, defines his glycolytic theory. The "ferment" is taken up by the leucocytes and carried by them to the tissues where it aids glycolysis. His experiments on artificial circulation have demonstrated the influence of a ferment in the blood on the consumption of sugar. An animal (a healthy dog) is bled to death; into one of the hind legs blood is transfused that is poor in glycolytic ferment (being taken from the vessels of a dog whose pancreas has been extirpated). Into the other leg blood rich in glycolytic ferment is transfused, being taken from a healthy animal. It is invariably found that the consumption of sugar is greater in the limb into which is transfused blood containing a normal amount of glycolytic ferment.

Operation for Congenital Dislocation of the Patella.—Dr. Bajardi describes the case of a child, aged four, operated on for imperforate anus when two days old. As soon as he began to walk it was noticed that he fell down unusually often, and especially when stooping to pick anything up, or when going up or downstairs. (*The British Medical Journal*). When the left knee was flexed beyond a certain point the patella would slip with a jerk to the outside of the knee. Both kneejoints presented a marked flattening of their anterior surfaces. The right patella was only slightly movable laterally, and it was impossible to move it into the median patella fossa. The left patella could be easily moved beyond the external margin of the external condyle, which was flatter than normal. There was no sign of genu valgum, and no history of injury. The dislocation could be produced at will and without pain. The chief causes of the dislocation were, 1, looseness of the internal capsular ligament; 2, flattening and outward inclination of the anterior surface of the external condyle; 3, partial atrophy of the vastus internus, allowing exaggerated action of the vastus externus. As the dislocation could be prevented, even when the knee was flexed, by pinching up the internal lateral ligament, Bajardi operated on the knee on November 25, 1892, excised a semi-lunar piece of the internal capsular ligament, and sutured the cut edges, thus shortening the ligament. A month after the operation the boy could walk without inconvenience and the dislocation has never recurred since. Bajardi has collected thirty-four other cases, and from a study of these he believes that congenital dislocation of the patella is generally due to anatomical deficiencies or abnormalities in the osseous or soft parts of the knee joint. In many cases the symptoms are so slight that the patient does not seek surgical advice; in others they get gradually better as the patient grows older. More severe cases, from the difficulty and insecurity of their walking, come into the surgeon's hands. A good kneecap suffices in many cases. The operative treatment must depend chiefly on the nature of the individual case and the particular cause of the dislocation.

Treatment of Artificial Anus.—Dr. Chaput records thirty-five cases of artificial anus and stercoral fistulæ which he has treated. After an exhaustive survey of these cases he has formulated the following conclusions concerning the treatment of this class of cases. He says that artificial anus can be treated by four different methods: 1. By the application of enterotomy, followed by obliteration of the fistula. (*a*) Enterotomy is indicated when the cases are uncomplicated and the aperture is easily accessible, together with a thin and long partition. When the spur is long and thin it is advisable to adopt Richelot's method—that is, section between two pairs of forceps and immediate suture. If, however, the spur is long and somewhat thickened, it is better to make the suture between two long pairs of forceps, which are allowed to remain in position. Enterotomy is contra-indicated when the spur is very thick or inaccessible, or when the aperture is closed by the mechanism of angular wounds. (*b*) After destruction of the spur, the stercoral fistula is closed. Small fistulæ are closed by lateral enterorrhaphy, during which operation the margins of the fistula are freely separated from their surroundings, and then united with two tiers of sutures, the peritoneum being opened or not according to the requirements of each individual case. In the case of large fistulæ lateral enterorrhaphy may be employed, but the peritoneum should not be opened. 2. Resection. Resection is, as a general rule, contra-indicated, but when in the course of a lateral enterorrhaphy the intestine is easily friable and is largely lacerated, it is necessary to resect the two ends and reunite them by appropriate sutures. 3. Longitudinal enterorrhaphy. When enterotomy is for some reason contra-indicated, it is sometimes advisable to employ

longitudinal enterorrhaphy without resection. This operation is done by making a circular incision in the skin around the artificial anus, and opening the peritoneal cavity. The two ends are drawn out, a longitudinal slit is made in each, and then the margins of the slits of the same side are sewn together with sutures. This operation is indicated when in the course of a lateral enterorrhaphy considerable constriction is met with just below the lower end. When the intestine is very friable it is contra-indicated. 4. Entero-anastomosis. Entero-anastomosis, followed by ligature of the two ends between the point of anastomosis and the stercoral aperture, is a simple, easy, and benign operation. It is indicated when the intestine is very friable at the seat of the artificial anus, or when there is a considerable constriction of the bowel in the neighborhood of the external aperture, and also when the inferior end is obliterated at the level of the artificial anus.—*Archives Générales de Médicine.*

The Surgical Treatment of Tumors of the Ileo-cæcal Region.—Dr. Körte recently read a paper on this subject (*Medical Press*). He said that the ileo-cæcal region was a point of predilection for the development of malignant tumors, and these were mostly in the form of carcinomas and local intestinal tuberculosis. The lumen of the gut was diminished and the glands were much enlarged. He had had 13 cases, 7 of which were operated on successfully; 2 of these, however, ended fatally in eight and eleven months later respectively. Three of the cases operated on were carcinoma, 3 tuberculous, and 1 actinomycosis of the cæcum. The last case was not recognized as such previous to operation. At the operation in this case an artificial anus had to be made. The disease had, however, extended to other organs, and the patient died exhausted eight months after the operation. The commencement in the case of malignant disease was very insidious. Generally the symptoms were those of typhlitis and copprostasis. Three of his cases had been sent to him from the medical side with the diagnosis of typhlitis. Suppuration frequently took place in the neighborhood of the bowel. These abscesses on being opened had characters differing from those of perityphlitic abscess. One passed into a cavity with hard walls, and they were less circumscribed, but they were difficult to distinguish from such perityphlitic abscesses. The history in these cases was very important. The diagnosis was frequently only made with the microscope. This was not very important, as the treatment was the same in all the classes of cases. As regarded treatment, resection and reunion of the divided parts were necessary. Symptoms of acute obstruction were contra-indications for resection and suture. Simple enterostomy was here called for with resection later on. The extent of the tumor might be prohibitory of operation. Another contra-indication was advanced cachexia. Of the 3 tuberculous cases 2 were hereditarily predisposed.

Recent Views on Diet in Diabetes.—Dr. R. T. Williamson, of Manchester, writing on the dietetic treatment of diabetes mellitus, points out that there are two well-marked forms of the disease—a mild form, amenable to a strict non-carbohydrate diet, and a severe form in which a strict diet does not arrest the sugar excretion. For some years, especially in Germany, the opinion has gradually been gaining ground that in the severe forms of diabetes a very strict diet is dangerous. Thus Leo has pointed out that a great increase of the nitrogenous metabolism, and, as a result, great loss of strength, occur in the majority of the severe cases of diabetes. Therefore treatment in such cases should be directed to diminish the sugar excretion, and also the nitrogenous metabolism. Leo demonstrated that, like the fatty foodstuffs, the carbohydrates have the power of diminishing the nitrogenous metabolism, and he has proved that, even on a carbohydrate diet, cases of severe diabetes manifest improvement and gain in weight, even though the excretion of sugar be increased. Leo considers that this improvement is in part due to diminished nitrogenous metabolism, to a limitation of albumin destruction, brought about by the albumin-sparing influence of the carbohydrates. The quantity of urine, the body weight, and the nitrogenous waste should be taken as guides in treatment, as well as the amount of sugar excreted. Hirschfeld has shown that in healthy persons acetonuria can be produced by a fatty and albuminous diet. The addition of carbohydrates prevents the occurrence of acetonuria. In cases where the carbohydrates are no longer burnt up in the system, a large quantity of acetone is often found in the urine, in spite of the carbohydrates in the food. Hirschfeld believes that diabetic coma is favored by the exclusion of carbohydrates in the diet. When the excretion of acetone is great, a strict diet ought not to be advised, but moderate quantities of carbohydrates should always be ordered. He also suggests the use of 100 to 150 grammes daily of glycerine in black coffee when early symptoms of coma appear. He does not recognize any form of acetonuria except the diabetic. Schmitz believes that diabetic coma is due to absorption of toxic substances consequent on the putrefaction of the undigested food in the intestines. We should therefore guard against giving an unduly large amount of animal food in diabetes, as the stomach is unable to digest such large quantities. He also points out the differences in the urine passed at night and during the day. Sugar appearing in the urine eight hours after a meal is formed from albuminates, and is a special sign of the severe form of diabetes. In the severe forms of diabetes Schmitz allows his patients to take food containing starch, and fat in large amount, but only a small quantity of albumin. He finds by such a diet that the general condition of the patient is much improved; the body weight and appetite increase, acetone and diacetic acid disappear in the urine, and in spite of the carbohydrates in the food, the sugar diminishes. Schmitz, Klemperer, and others have directed attention to the great value of cod-liver oil as a fatty food in diabetes. This is an old remedy which has not been largely employed in the treatment of diabetes. If the patient resents the cod-liver oil, liparine may be substituted. Starch is the only carbohydrate Schmitz would allow; all fruits and sugars he considers injurious. Schmitz, therefore, in severe cases would allow starch-containing food, which he considers of importance; but he would limit the amount of animal food. In the mild cases he would reverse the treatment, and withdraw carbohydrates from the food. Grube believes that the only way to prevent the acetonuria developing into diabetic coma is by impregnating the system with carbohydrates. Dr. Williamson next refers to the breads suitable for diabetic patients. He considers the home-made preparations as reliable, and less expensive and more palatable than the advertised breads. Ebstein recommends aleuronat. This is a vegetable albumin prepared from wheat. By the addition of ordinary flour, bread can be prepared from this substance. The following are Ebstein's directions for the preparation of bread: Take about 7 ounces of white flour, about 7 ounces of aleuronat, about five ounces of butter, one teaspoonful of salt, and 310 grains of baking powder. The flour and aleuronat are first mixed in a dish warmed to about 30° C., the melted butter and lukewarm milk gradually added, then the salt, and finally the baking powder. The dough is well mixed, formed into loaves, and baked at a good heat. Dr. Williamson has had palatable and cheap cakes made as follows: 2 ounces of finest desiccated cocoanut powder, 2 ounces of aleuronaut, 1 egg, and a little milk. The egg is beaten up, and the aleuronat and cocoanut powder added together with a little milk. The mass is stirred until a dough is formed. This is cut into thin cakes and baked.—*Med. Chronicle.*

LEUCOCYTOSIS IN PNEUMONIA.

As long ago as 1839 Piorry noticed that cases of croupous pneumonia were accompanied by a noticeable increase of white corpuscles in the blood. The practical significance of his observations was not, however, considered very great. Dr. Billings has recently made some new studies on this subject, which appear in the *Johns Hopkins Hospital Bulletin*. He reminds us that Virchow, in 1871, spoke of a leucocytosis in pneumonia, and held that there was an actual new formation of leucocytes, *i.e.*, an absolute increase in the total number present in the circulation, but only in those cases in which there was swelling of the bronchial glands.

Since then there have been many investigations on the subject, especially in the last four years. Nasse, Koblanck, Sörensen, and Pée all noted the presence of a leucocytosis during the course of croupous pneumonia, but they did not speak of its relation to the temperature, nor to prognosis.

Halla, in 1883, was the first to report a series of cases, 14 in number. In 12 of these there was a leucocytosis, while in the remaining 2 the leucocytes were not increased. Both the latter cases ended fatally. He was the first to call attention to the fact that the absence of leucocytosis is of bad omen. He found no correspondence between the temperature and leucocyte curves in those cases ending in recovery.

Hayam and Gilbert, in 1884, remarked upon the typhoid character of those cases of pneumonia in which there is no leucocytosis.

Tumas, in 1887, stated that there was a rough daily correspondence between the temperature and the leucocytes, and that the number of the latter was greatest at the severest stages of the disease. He also noted that the leucocytes did not reach normal at the same time as the temperature, but remained elevated for three or four days after the crisis.

Boekmann and Von Jaksch claim that there is a constant relation between the number of leucocytes and the temperature in various acute infectious diseases, and particularly in pneumonia.

Kikodse states that leucocytosis is absent only in fatal cases. He believes that the leucocytosis begins before the involvement of the lung takes place, that it runs parallel with the temperature, and falls to a point below normal with the crisis in temperature.

Romer believes the leucocytosis in pneumonia to be caused by the products of destruction (bacteria, cells, etc.) brought about by the alkali-proteins, and not directly by the alkali-proteins themselves.

Von Jaksch, recognizing the bad prognosis in cases which showed no leucocytosis, and believing that the fatal termination was due directly to its absence, recommended the use of drugs which would produce an increase in the number of leucocytes in the blood (antipyrin, pilocarpin, etc.). Such treatment was ineffectual, as will be demonstrated later.

Other observations record similarly conflicting views.

Dr. Billings bases his personal views on the study of 22 cases of pneumonia, of which number 12 recovered and 10 died. Of the 10 fatal cases only 1 (No. 20) showed a complete absence of leucocytosis during the entire course of the disease. In Cases 16 and 19 the leucocytes, while being always above normal, ranged relatively low, never being above 19,000. In Case 14 the leucocytes behaved as one would expect them to in an uncomplicated case ending in recovery. In Cases 15, 17, and 21 the leucocytes were practically normal on admission, but gradually rose during the ensuing three or four days, touching just before death 30,000, 32,000, and 30,000, respectively. In Cases 13 and 22 the leucocytes were high on admission, but fell steadily from that time on until death. In Case 18 they were normal for the first two days, but rose sharply to 20,000 twenty-four hours before death, falling slightly just before the end.

Thus we see that in fatal cases the behavior of the leucocytes varies widely. In six cases there was absence of leucocytosis at some period of the disease, but the continuous absence is the exception, not the rule. In none of the cases was there any daily correspondence between the temperature and leucocyte curves. In the four cases in which the leucocytes rose at the end, however, there was a corresponding rise in temperature. As regards the relation of the amount of leucocytosis to the extent of lung involvement, no definite conclusions can be drawn. In Case 15, where the entire right lung and a portion of the left were involved, the maximum leucocytosis was only 30,000 just before death. None of the cases were seen until at least twenty-four hours after the chill, so that no data are furnished as to how early the leucocytosis appears.

The final conclusions of Dr. Billings are given as follows:

1. In cases of pneumonia pursuing a favorable course there is, as a rule, a marked increase in the number of the leucocytes during the febrile period of the disease. This leucocytosis is probably present at the time of the chill, and may be very marked within a few hours. There is no correspondence between the daily temperature and leucocyte curves during the febrile period.

2. In those cases in which the temperature curve falls by crisis, the leucocyte curve begins to fall within a few hours of the same time. The fall of the latter is only partial, however, and rarely reaches normal as soon as the temperature curve, generally taking about forty-eight hours longer. In cases ending by lysis the two curves fall together, the temperature always reaching normal first. In cases of delayed resolution the leucocytes may remain elevated for days.

3. In a majority of the cases the leucocyte curve

rises during the period of fall of temperature, and may reach its maximum at that time. Such a rise is only transient, however, and is soon followed by a fresh fall.

4. In cases showing extensive involvement of both lungs, the leucocytes are apt to reach a higher point than in those cases where the involvement is only moderate. The correspondence of lung involvement and amount of leucocytosis is a very rough one, however.

5. The fatal cases may show either the presence or absence of leucocytosis. In those cases showing a leucocytosis, some other cause of death than the virulence of the bacterial poison must be sought for.

6. The prognosis in cases showing a complete and continuous absence of leucocytosis is unfavorable as a rule. A continuous absence of leucocytosis is the exception, most cases showing a leucocytosis at some period of the disease. The possibility of the absence of leucocytosis being due to extreme mildness of the disease must not be overlooked.

7. The leucocytosis in pneumonia is a so-called pure leucocytosis, *i.e.*, an increase in the polynuclear elements solely. In cases showing no leucocytosis, the blood condition, according to the observations here reported, is normal. Further investigations are necessary before the work of previous observers can be positively contradicted.

8. The presence or absence of leucocytosis only shows the virulence of the bacterial poison. It is not a criterion of absolute prognosis.

THE CONSUMPTION OF NARCOTICS AND STIMULANTS.

In these days when so much is being said about the degeneracy of the race, it is interesting to learn that there are some signs which, if not very promising, are at least not altogether bad. We refer to the facts brought out concerning the consumption of beer and spirits in Great Britain. According to a recent Parliamentary report the consumption per head of tea in 1861–62 was 4.38 pounds; in 1893 it was 6.90 pounds yearly. In regard to wines and spirits the total amount consumed in 1861–62 was 35,000,000 gallons, or [illegible] respectfully urge upon the Legislature increased in session the passage of an act by which the existing Departments of Charities and Correction in the city of New York shall be abolished, and two separate and distinct departments be created, one of Charities and one of Correction."

Diphtheria Antitoxin.—The following papers, to be found on pages 481 *et seq.*, were then read: 1, "Some experiences in the Production and Use of Diphtheria Antitoxin," by Dr. H. M. Biggs; 2, "The Technique of the Production of Diphtheria Antitoxin," by Dr. W. H. Park; 3, "Experiences in Diphtheria Antitoxin for Immunization," by Dr. G. H. Peck; 4. "The Autopsies on Persons Dying after Treatment with Diphtheria Antitoxin," by Dr. George P. Biggs.

Opposed to Antitoxin.—Dr. Joseph E. Winters, in opening the discussion, said:

Mr. President: Some months ago I shared with my colleagues the hope that a specific against the toxins of the diphtheria bacillus had been discovered, but three months of daily observation in the Willard Parker Hospital has been a sad—an extremely sad disappointment to me, and I regret to say that, as a result of that experience, I am here to-night to speak in opposition to the antitoxin treatment of diphtheria. My remarks will be

THE PATHOLOGICAL HISTORY OF TWINS.

The family history of twins is a subject the study of which offers much that is interesting and worthy of the attention especially of neurologists. In families where twin births are frequent, it has several times been noted that cancer was one of the prevailing diseases among those born singly, while the twins were especially prone to suffer from nervous affections. Critzman has reported in the *Bulletin Médical* for 1894, p. 983, a family in which all the members not twins suffered from cancer, and Féré has related a somewhat similar history in a communication made to the Société de Biologie in December, 1894.

Of this family a complete history could be obtained only for three generations, but it was said that the great-grandmother had had many relatives in the ascending and collateral branches of the family who were twins. The great-grandmother of this family died at the age of fifty-two of cancer of the uterus, after giving birth to four children, two of whom were twins. One of the latter was epileptic and died at the age of twenty-two during a convulsion. The other twin had melancholia and committed suicide at the age of forty-seven years. One of the other children died of cancer of the uterus in her forty-ninth year, after twice bearing twins, all of whom died in convulsions during infancy. The remaining child, a male, was the father of two children. He died of some acute malady, possibly pneumonia, in his fifty-fifth year. One of his children died unmarried at the age of fifty-one years of cancer of the stomach. The second child, Madam G——, died at the age of fifty-nine of what was said to be liver disease. She had three children, one of whom is living in good health, unmarried. The other two children were twins and are both living, one epileptic, the other suffering from agoraphobia.

Thus there were among three generations of the descendants of one woman four sets of twins, all of whom were the subjects of some nervous malady. Of the six born singly, including the great-grandmother, three died of cancer and one of hepatic disease, which may have been cancerous. Dr. Féré does not bring forward his cases as corroboration of the theory of the origin of cancer advanced by Critzman, but simply reports the facts, laying particular stress, however, upon the prevalence of nervous affections among the twins.

ANOTHER CONSUMPTION "CURE."

The United States Consul at Berlin has sent home to Washington an account of an alleged cure for consumption, discovered by Dr. Louis Waldstein, of this city. The text of the Consul's letter is printed elsewhere. This text shows that the ingenious inventor has not yet discovered a cure, but only a theory of a cure. The theory is this:

"By successive injections of minute doses of pilocarpine in the veins, he arrives at a gradual stimulation of the lymphatic system. That system increases the white corpuscles in the blood, which corpuscles, as is well established through Metchnikoff, of the Pasteur Institute of Paris, Hankin of Cambridge, and Buchner of Munich, in some way, not generally agreed upon, do

certainly overcome and cause to be harmless those poisonous particles in the blood which produce disease. Metchnikoff thinks that the microbes which destroy the red corpuscles of the blood are swallowed and englobed alive by the white corpuscles. Hankin and Buchner think that the white corpuscles merely absorb the dead microbes, and therefore call the white corpuscles 'alexine,' or protective particles. Dr. Waldstein goes to the fountain whence these white corpuscles spring, and tries to enliven its action and productiveness when, through disease, these health-giving particles have become too few to keep the blood in proper order."

Dr. Waldstein has not yet tried this theory in pulmonary tuberculosis, but in one case of lupus of the hand the results are spoken of as extraordinary.

We cannot but feel the strongest scepticism of the alleged discovery; and it is unfortunate that, if there is merit in it, the matter should be made a subject of governmental correspondence and newspaper advertising, on the strength of, as it appears, a single case.

Lupus runs a very curious course, and we all recall the occasional subsidence of the disease under injections of tuberculin and cantharidin, as well as in thyroid feeding.

The basis of the theory itself is weak, for we know that in those conditions in which the white blood-cells are excessively numerous, such as leukæmia, the patients are ill and show no increase in vital resistance.

Our consuls should find better employment than in advertising new remedies and in endorsing sensational therapeutic theories.

FURTHER STATISTICS IN REGARD TO DIPHTHERIA ANTITOXIN.

At the Congress of Internal Medicine which recently met in Munich, Dr. O. Heubner communicated new statistics regarding the effects of the heilserum. In a total of 3,000 cases, collected from different parts of the world, the mortality was twenty per cent. Among 207 cases treated at Charité Hospital the mortality was thirteen per cent., and among the 181 pure cases, ten per cent. Relapses occurred in 1.6 per cent., and paralysis in 7.4 per cent.

Baginsky reported that at the Kaiserin Hospital the mortality, which used to range about forty per cent., has been reduced to thirteen per cent. Baginsky also stated that among 59 families 124 children were inoculated for immunizing purposes, and that in no case did diphtheria occur. Widerhoper, of Vienna, stated that among 300 cases the mortality was 23.7 per cent., this being a much lower death-rate than had previously existed. Among 130 children who were immunized only 1 caught the disease.

Ranke, of Munich, found that under serum-therapy the mortality-rate fell from forty-two per cent. to 18.6 per cent. Several others gave reports of about the same character, and all expressed a belief in the therapeutical efficiency of the serum.

A Thing of Culture.—The bacillus.

News of the Week.

Death of Dr. Benjamin F. Westbrook.—Dr. Benjamin F. Westbrook, a well-known physician of Brooklyn and contributor to the Medical Record, died at his home, 91 Division Avenue, Monday, of pneumonia. He was born in St. Louis on February 4, 1851, and was graduated from the Long Island College Hospital in 1874 at the head of his class. Five years later he was a member of the junior faculty, teaching anatomy and surgical pathology. He was visiting physician to the Methodist Episcopal Hospital and to St. Mary's Hospital for a number of years, and was a member of the American Climatological and American Laryngological Societies, of the New York Academy of Medicine, and of several of the Brooklyn medical societies. He was a contributor to medical literature, and devised a method of drawing blood from the overcharged right side of the heart with a fine, hollow needle in otherwise hopeless cases of pneumonia. For a year he has been writing extensively on a system of therapeutics, and at his death was engaged on a large work on medical diagnosis.

Death of Dr. A. S. Sally.—Alexander Samuel Sally, of Orangeburg, S. C., died April 1, 1895, aged seventy-seven years. Among the representatives of the highest type of the Southern physician Dr. Sally stood foremost, not only because of his attainments in his chosen calling, but because of his kindly, generous, chivalric nature. Indifferent almost to carelessness to the financial aspects of his calling he labored for fifty years among the swamps and hamlets of Orangeburg County in South Carolina, in which his name had become a household word. During the war he occupied a high position as a surgeon; and he won the esteem of his comrades, from the humblest to the highest, by his unselfish devotion to their welfare. His interest in the younger members of the profession was a distinguishing characteristic; his example to those of the present generation who fell within the sphere of his personal influence was wholesome and ennobling. He left a widow and seven children, one of whom is a physician.

least twenty-four hours after the chill, so that no data are furnished as to how early the leucocytosis appears.

The final conclusions of Dr. Billings are given as follows:

1. In cases of pneumonia pursuing a favorable course there is, as a rule, a marked increase in the number of the leucocytes during the febrile period of the disease. This leucocytosis is probably present at the time of the chill, and may be very marked within a few hours. There is no correspondence between the daily temperature and leucocyte curves during the febrile period.

2. In those cases in which the temperature curve falls by crisis, the leucocyte curve begins to fall within a few hours of the same time. The fall of the latter is only partial, however, and rarely reaches normal as soon as the temperature curve, generally taking about forty-eight hours longer. In cases ending by lysis the two curves fall together, the temperature always reaching normal first. In cases of delayed resolution the leucocytes may remain elevated for days.

3. In a majority of the cases the leucocyte curve

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 4, 1895.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Portrait of the Late Dr. Valentine Mott.—An oil portrait of the late Dr. Valentine Mott, copied from an original painting made in 1865, the gift of his daughter, Mrs. Isaac Bell, was presented, in a few appropriate words, by DR. ELY, at whose suggestion Mrs. Bell had had the copy made.

THE PRESIDENT, in some remarks accepting the generous and highly prized gift, said one could not express more forcibly the debt of the profession to Dr. Mott than to quote the words of Sir Astley Cooper, that Dr. Mott had probably performed more and greater operations than any living man.

The Late Dr. Loomis.—DR. POLK, of the Special Committee, read some resolutions on the death of the late Dr. Alfred L. Loomis, which will be found on another page. The meeting set apart for the memorial exercises will be held on the first Thursday in May, not the first Thursday in June, as announced previously.

Department of Charities and Correction.—DR. ANDREW H. SMITH, of the Special Committee appointed to consider the Advisability of separating the Department of Charities and Correction, read a report setting forth at some length reasons why there should be a division into two entirely distinct departments of the city's dependents and its criminals. The arguments were based upon such well-known facts as that the combined department had become unwieldly; the original act had contemplated their separation; there was no natural law of association of the dependents (including the poor, the sick, the blind, the insane, etc.) with the criminals; no official board could become expert in both branches, and indeed the very qualifications which fitted an officer for dealing with criminals unfitted him for dealing with dependents. To be sent to the "Island" cast a stigma upon the innocent dependent the same as upon the criminal; appropriations were refused the one class because associated with the other. The report concluded with the following resolution, which was adopted without opposition: "Resolved, That the New York Academy of Medicine respectfully urge upon the Legislature now in session the passage of an act by which the existing Departments of Charities and Correction in the city of New York shall be abolished, and two separate and distinct departments be created, one of Charities and one of Correction."

Diphtheria Antitoxin.—The following papers, to be found on pages 481 *et seq.*, were then read: 1, "Some experiences in the Production and Use of Diphtheria Antitoxin," by Dr. H. M. Biggs; 2, "The Technique of the Production of Diphtheria Antitoxin," by Dr. W. H. Park; 3, "Experiences in Diphtheria Antitoxin for Immunization," by Dr. G. H. Peck; 4. "The Autopsies on Persons Dying after Treatment with Diphtheria Antitoxin," by Dr. George P. Biggs.

Opposed to Antitoxin.—DR. JOSEPH E. WINTERS, in opening the discussion, said:

MR. PRESIDENT: Some months ago I shared with my colleagues the hope that a specific against the toxins of the diphtheria bacillus had been discovered, but three months of daily observation in the Willard Parker Hospital has been a sad—an extremely sad disappointment to me, and I regret to say that, as a result of that experience, I am here to-night to speak in opposition to the antitoxin treatment of diphtheria. My remarks will be based entirely on three months of daily clinical observation of the effects of the antitoxin in one hundred and fifty-four cases of diphtheria treated in the Willard Parker Hospital. In the paper of the evening reference has been made to the effects of the antitoxin on the pseudo-membrane of diphtheria. What I have to say with reference to this may be best illustrated by referring to four cases which were recently admitted into the Willard Parker Hospital in the course of one day.

Case I. had a few patches of pseudo-membrane in various portions of the throat, showing that the exudate had already exfoliated, only small portions of it remaining.

Case II. had pseudo-membrane on both tonsils, which was thick at the edges, and exfoliation had already begun, in some places being detached from the mucous membrane one-eighth of an inch.

Case III. was in the early stage of the disease process. The pseudo-membrane was thin at the edges, involving the tonsils and slightly the pillars of the fauces. At one point there was inflammation at the edge of the pseudo-membrane.

Case IV., a septic case, with an abundance of membrane on the tonsils and pillars of fauces and some on posterior wall of pharynx.

In Case I., where detachment of membrane was nearly complete before patient was brought to hospital, the throat cleared rapidly. In Case II. the exfoliation, which had begun at the time of admission of the patient, continued, but some membrane remained on pillars of fauces and on tonsils ten days after admission. Case III. was free from membrane for first time on tenth day after admission. Case IV., the septic case, lived three days. During this time, though thoroughly under the influence of antitoxin treatment, the antitoxin never made the slightest impression on the symptoms of toxæmia. These four cases may be taken as a sample of what I have seen repeatedly at the Willard Parker Hospital during the three months of antitoxin treatment of diphtheria. In not a single case has there been the least evidence that the formation of the pseudo-membrane was checked, that the exfoliation of the pseudo-membrane was hastened, or that the throat was free from membrane earlier than in cases which have not been treated by antitoxin. In not a single septic case has the antitoxin made the least impression on the symptoms. The toxæmia has not in one instance been relieved or lessened. There has been no indication in the character or frequency of the pulse, or in the general condition of the patient, that a specific for the toxæmia had been administered.

Reference was next made in the paper of the evening to the laryngeal cases of diphtheria, and I should like to ask the author of the paper and those who are supporters of the antitoxin treatment, why it is that antitoxin should be administered for the relief of the laryngeal stenosis due to a diphtheritic pseudo-membrane? While the diphtheritic process remains confined to the laryngeal mucous membrane there is no toxæmia. There is, therefore, no indication for the exhibition of an antitoxin. It has been stated in the paper that the death-rate in the laryngeal cases under the antitoxin treatment has been lower than under the methods of treatment in vogue before the use of antitoxin, but in so doing he compares results one year ago with the results during the past three months. The author has neglected to state to the Academy that at the Willard Parker Hospital, in the month of December last, we had eight *consecutive* recoveries after intubation in cases of laryngeal diphtheria without antitoxin. During the same month at the Foundling Asylum in this city, out of fourteen cases of intubation for laryngeal diphtheria there were twelve recoveries without antitoxin. At the Willard Parker Hospital in the month of December, 1894, the recoveries from laryngeal diphtheria without antitoxin were about seventy-five per

cent. This has never been equalled with the antitoxin treatment with or without intubation.

The paper of the evening deals largely with statistics. I wonder if the members of the Academy have noticed that the author treats the matter of statistics largely by elimination and exclusion. In comparing the results of antitoxin treatment with the former methods of treatment, in the antitoxin cases he excludes numerous deaths for one or another reason, while in speaking of the results before antitoxin treatment no deaths are eliminated. The facts are that during the first three months of 1894 the death-rate at the Willard Parker Hospital without antitoxin was thirty-two per cent. During the first three months of 1895 with antitoxin treatment the death-rate was twenty-eight per cent. But in order to make it clear to you that this mortality rate does not represent the exact state of things as it should, I will ask you to consider for a few moments the class of cases which have been brought into the Willard Parker Hospital for antitoxin treatment during the past three months. In many of these cases there has been no clinical evidence of diphtheria. They were cases of diphtheria from the bacteriological stand-point only. Examination of the nose and throat, examination of the constitutional condition of the patient, revealed no evidence of diphtheria. They had in the throat the Klebs-Loeffler bacillus, but the presence in the throat or in the nose of this bacillus, in the absence of any lesion, is not evidence of the existence of diphtheria. *I should like to know why antitoxin is used in cases where the presence of the Klebs-Loeffler bacillus is the only evidence of diphtheria, when it is a well-established fact that the antitoxin treatment has no influence on the bacillus—it persists as long in cases treated with antitoxin as it does in cases treated without it.*

During the first three months of 1894 no case of diphtheria was seen in the Willard Parker Hospital that did not have abundant clinical, as well as bacteriological, evidence of diphtheria. These cases of so-called "diphtheria" without any of the clinical manifestations of the disease, should be eliminated from the statistical report, and there have been a score or more of such cases during the past three months, and were these cases eliminated from the list, the death-rate under antitoxin treatment during January, February, and March would be much higher than it was during the corresponding months of 1894; and this, too, at a time when diphtheria is far milder than it was one year ago. Some of the cases brought to the hospital in February and many of those admitted in March are still very ill and will surely die. Were these included, the mortality during the antitoxin treatment would be startlingly high.

The author of the paper, like all others who have written about the antitoxin treatment of diphtheria, has insisted upon early treatment as a *sine qua non* for the best results, but the record from which Dr. Biggs has prepared his paper will show that the first two cases on the list which recovered had their first injection of antitoxin on the eighth and sixth days respectively.

In the next seven cases on the list the first injection was given on the fourth day in two cases, on the fifth day in two cases, on the third day in two cases, on the sixth day in one case, and all died. Case XXIV. on the list had first injection on the ninth day and recovered. One case, injection on second day, died. One case, injection on tenth day, got well, and one injected on the third day died; and so on throughout the list. It is not the date of first injection which determines the result, but it is the individual character of the case and the nature of the disease.

At the Willard Parker Hospital any case which, at the time of admission, has given evidence that the disease was progressive in its course, that course has not been stayed or changed in any particular by the antitoxin treatment.

It has also been stated that the serum used in the early part of the antitoxin treatment at the Willard Parker Hospital was so weak that little could be expected from it. A careful study of the record will show that the cases which were treated with the weaker serum did better than those which were treated with the stronger serum. Again, a study of the records will show that those who had the smaller dose of serum did better than those who had a larger dose. In fact, a careful study of the individual cases of diphtheria treated with antitoxin in the Willard Parker Hospital will show that there has been no relation between the antitoxin treatment and the recoveries. As to the early treatment of diphtheria with antitoxin, it may be definitely and confidently stated that diphtheria at the present time, almost invariably recovers under any method of treatment if brought under proper hygienic surroundings and surveillance on the first day of the disease. Diphtheria is scarcely ever fatal if the patient is put to bed and properly cared for on the first day of the illness. It is the *insidiousness* of diphtheria which constitutes its greatest danger.

Now as to some of the untoward or unfavorable effects of the antitoxin treatment. The rashes have been spoken of in the paper, and some of the minor features attributable to antitoxin, but the more serious effects of the antitoxin treatment have not been alluded to.

I will ask you to go with me for the time being to the Willard Parker Hospital and see some of the effects of antitoxin which I have witnessed there. Babies have been brought to that hospital with slight clinical evidence of diphtheria, babies, with the exception of a slight exudate in the throat, and perhaps a slight croupy cough, that were apparently healthy and with rosy color. They remained in good condition for perhaps ten days or two weeks after receiving antitoxin, when one day as you enter the ward you hear a moan, and approaching the crib you find the baby lying on its side with its head retracted, its arms and legs flexed, and moaning piteously. I can best make it clear to you what this baby's condition is by relating to you a case about which I was consulted. A physician came to my office to advise with me regarding his wife. Two weeks previously this lady had had a slight sore throat, and a medical friend had immediately injected her with antitoxin. The following day it was decided that she had no diphtheria, but a slight tonsillitis, and the throat was all but well. Fifteen days after the injection of antitoxin her temperature was 105° F., pulse 160, and she was suffering severe pain in all her joints. Sleep and rest were absolutely impossible except as obtained by large doses of morphine administered hypodermically. This was a case of antitoxin infection. In her case the antitoxin eliminated itself and the patient recovered. This is the condition in which I have seen many of the little babies in the Willard Parker Hospital. The temperature chart shows a record of 105° to 106.8° F., and a note of the night nurse tells that the patient has scarcely slept at all. This antitoxin infection pursues one of two courses, either the symptoms may gradually subside, leaving the baby emaciated and extremely anæmic, or there may be a fluctuating temperature, ranging from 99° to 106.8° F. and existing for days together. What is this condition? It is due to the action of the antitoxin on the blood. *Horse serum dissolves human blood corpuscles, and thereby produces new elements of decomposition. The condition of the babies just spoken of was one of antitoxin septicæmia, and brought about by the influence of the antitoxin on the blood.* A further evidence of septicæmia was in occasional suppurations, as seen in one case in the neck and ear, in another in small points of suppuration in various portions of the body. In these cases we have a temperature range such as has not been seen in the hospitals of this city since the introduction of aseptic surgery. This is a temperature

range such as we used to have in the surgical and maternity wards of Bellevue Hospital twenty years ago.

It has been said here to-night that many of these cases treated with antitoxin have not died from diphtheria; that an autopsy has proven that the babies had recovered from diphtheria, and that the lesions proved that they had died of pneumonia after recovery from diphtheria. *This pneumonia in the Willard Parker Hospital during the past three months has come on late in the course of the disease, and they have been such pneumonias as were seen in Bellevue Hospital when they were having a great deal of septicæmia there. They are the pneumonias of septicæmia, and this septicæmia was induced by antitoxin.*

A second form of antitoxin infection was seen in the case of a little girl, aged thirteen months, admitted March 22d. Given the first injection of antitoxin immediately; temperature before injection, 101.6° F. Temperature six hours after injection, 104° F. Second injection, March 23d; afternoon of same day, kidneys ceased to act. Hot pack and other methods of treatment resorted to. Baby died, in spite of all treatment, on the afternoon of March 26th.

Dr. Lennox Browne has reported a total of eight cases of diphtheria treated with antitoxin; death resulted in six cases, all due to inflammation of the kidneys. Benda found nephritis in thirty-three cases out of thirty-nine who had died under the antitoxin treatment.

An instance of antitoxin infection through its action on the nervous centres occurred in a baby, aged two years and four months, admitted March 19th. Temperature, 101.2° F. on admission. First injection of antitoxin at 6.30 P.M. Baby had restless night. At 5 A.M., on the 20th, temperature was 105° F.; at 5.45 A.M. baby was in convulsions, and died at seven o'clock in convulsions, death resulting thirteen hours and fifteen minutes after injection of antitoxin.

The third case of immediate bad result with antitoxin was in a baby, aged eleven months, admitted March 29th. Temperature, 101.8° F. on admission. First injection, day of admission; second injection, following day. About twenty-four hours after admission, baby's temperature was 105.8° F.; convulsive movements of the eyes were noticed. Careful examination revealed no evidence of organic disease. Baby was in semi-stupor, respirations twenty-eight to the minute. Pulse rapid, irregular, and intermittent. March 31st, temperature, 106.8° F.; convulsions general. Baby died 2.30 A.M., April 1st, in convulsions. Temperature, 108° F. an hour before death.

Autopsies asked for but not granted in any of these cases. Physical examination revealed no evidence of organic disease in either of these cases; they were unquestionably cases of antitoxin poisoning.

This brings us to one of the most important considerations in connection with the subject of antitoxin treatment of diphtheria, namely, individual susceptibility to the action of remedies.

There is in this room to-night a physician who, about a year ago, came very near dying from the influence of a single dose of $\frac{1}{100}$ grain of atropine. He is organically healthy, and was well at the time with the exception of a slight coryza. Anyone of us in this room might have taken the same dose or double the amount without suffering any ill effects. This is one instance of individual susceptibility. As we all know, one person is specially susceptible to the influence of morphine, another to the influence of atropine, and so on throughout the entire list of remedies. So some individuals are specially susceptible to the influence of antitoxin. When this susceptibility exists or to what extent can never be known beforehand. It was the existence of this special susceptibility which caused the antitoxin to produce its fatal effects in the cases here enumerated. It was the existence of this special susceptibility or idiosyncrasy in the case of Miss Valentine which caused her unfortunate death from a single injection of antitoxin. That the antitoxin which was used in her case was all right in every way has been officially certified to by the Board of Health of this city and of Brooklyn. The fault was not in the antitoxin used, but in the special susceptibility of the patient. This same antitoxin might have been used on another person without producing any ill effect. We know nothing of this individual susceptibility beforehand, and any physician who uses antitoxin takes the risk of bringing about the results which I have described to you as having occurred in the Willard Parker Hospital, and the result which occurred in the case of Miss Valentine.

A case parallel to these is reported in the *British Medical Journal* of March 2d, p. 505. A well child, three years of age, was given an immunizing dose of 2 c.c. of No. 1 Behring serum. The next morning the child was depressed. On the following day she had fever and violent pain in the lumbar region, and the urine contained a considerable quantity of albumin. The next day the temperature was 103° F.; petechiæ appeared on the legs, and the day after the child died.

In summarizing, I oppose the antitoxin treatment of diphtheria first, because in an experience of one hundred and fifty-four cases during the months of January, February, and March, 1895, in the Willard Parker Hospital, I have failed to see the slightest evidence that it neutralized the toxæmia in a single case. I have never found that it exerted the slightest influence for good in a single clinical manifestation of the disease—on membrane, pulse, temperature, gland swelling, laryngeal symptoms, etc. Everyone of these cases has been examined daily; they have been examined with care and with great solicitude, and with a desire to discover some evidence of the virtues ascribed to antitoxin by others.

Secondly, *I oppose it on account of its immediate danger to life, through its influence on the kidneys and on the nervous system, and remotely, through its influence on the blood.*

Conservative.—Dr. George L. Peabody thought there was sufficient evidence so far collected to show that in the antitoxin treatment of diphtheria we had a complicated problem to deal with. To judge of the result we must know all the facts bearing upon each particular case. As Dr. Winters had stated, the bacteriological diagnosis was often unsatisfactory. He had, for instance, given an injection of antitoxin to a governess with a sore throat suspected to be diphtheritic, and sent cultures from her throat and that of several children with whom she had come in contact to an able bacteriologist, and the report was that the Klebs-Loeffler bacillus was in all the cultures but one, the exception being that of the governess. None of the children were sick. But that did not invalidate bacteriological work. It was a serious problem what to do with persons in a house where there was diphtheria who themselves had simply the Loeffler bacillus in the throat. Personally he would not be willing to expose such a person to the contagion of a hospital ward, yet he would not be willing to give him a clean bill of health and permit him to associate with others. The bacillus might be present, yet the person escape for want of receptivity.

His personal experience with antitoxin had been limited, yet he had convincing proof of its value, having seen the membrane melt away under a single injection as it had never done before under either local or constitutional treatment. He had seen untoward symptoms in a young lady injected by a physician in New Jersey. The throat cleared up promptly, but six days after treatment an urticarial eruption came out, and the patient suffered a week with symptoms of septicæmia, such as rapid fluctuations of the temperature, sweating, prostration, and pains in the joints. She ultimately recovered entirely. There was such convincing evidence of the value of the remedy from unbiased

sources, especially from Europe, that he could not but feel that it was deserving of credence.

Favorable Testimony.—Dr. L. Emmet Holt was satisfied that the antitoxin treatment of diphtheria was of value. Up to this time he had seen no bad results. His experience had been limited to twenty cases, all in small children in institutions except two. Every case had got well except one, that of a marasmus child. He repeated that he had seen no unfavorable symptoms, and if he himself had a child with diphtheria he would inject it with antitoxin.

Dr. Somerset, referring to Dr. Winters's remarks as to the mild character of the cases treated at Willard Parker Hospital, said that, of course, the hospital was not conducted for the purpose of making statistics for antitoxin treatment, but rather for the purpose of taking care of diphtheritic patients sent there, and under instructions from the Board of Health all the cases were, according to the best judgment of those in charge, treated by antitoxin. Certain cases having been referred to as mild cases, with rosy cheeks and croupy cough, Dr. Somerset said he could not recognize in a case of croup one of mild diphtheria. As to cases dying within twenty-four hours, he thought that was the rule, rather than the exception, in cases of croup. As to certain ill effects ascribed to antitoxin, he had been in Willard Parker's sixteen months, and could remember very well that before the use of antitoxin cases occurred in which there were irregular rises of temperature, rashes, and symptoms regarded more or less unfortunate. They were then ascribed to digestive disturbance, while now antitoxin got the whole credit. As to the influence of antitoxin in fatal croup cases, he had compared twenty-four such fatal cases during the pre-antitoxin period with the same number since, and had found that all of the former deaths had occurred within six days, while only half of the deaths under antitoxin treatment had occurred by the sixth day. Without antitoxin treatment membrane was found below the larynx usually, while in none of the autopsies on cases dying after antitoxin treatment had he seen membrane below the larynx. In the first class, if pneumonia developed it was in the first four or five days, in the second, it did not appear until much later as a rule.

Dr. Winters made some further remarks, and said that the pneumonia coming on after antitoxin treatment appeared late, occurring with or after evidences of septicæmia.

Defends His Statistics.—Dr. Herman M. Biggs made some concluding remarks. He said Dr. Winters had omitted to explain why the mortality from diphtheria under the antitoxin treatment, even if nothing were eliminated, was still ten per cent. lower than it was last year. Could one who was an unprejudiced observer, make the statement that there was little diphtheria of a severe type in New York when the statistics showed that there were two thousand eight hundred deaths from the disease for the year ending January 1, 1894? Many statements, and many inferences drawn by Dr. Winters were, he said, distinctly untrue. It had been asserted in a very dramatic manner that of septic cases treated in the hospital with antitoxin, not one had been improved. In reply it had been sufficient to say that from the beginning it had been shown that antitoxin was only of value to neutralize diphtheria toxin; it did not neutralize sepsis, it did not neutralize bronchopneumonia.

He would like to know where Dr. Winters's information came from that there was no absorption from the larynx. Antitoxin did good in croup cases because it neutralized diphtheria toxin; it reduced the inflammatory swelling, and it prevented extension of membrane.

In reply to the statement that the statistics were the result of a process of elimination, he would say that no cases were eliminated except those which died within twelve hours, with two further exceptions. Cases dying within twelve hours were justly eliminated because antitoxin was not expected to exert its influence immediately; it did not produce its effects for twelve hours.

The two other cases which were eliminated were cases in which the treatment was discontinued. As to the severity of the type of disease existing since antitoxin treatment had been introduced, he could prove by statistics that the severity was greater than prior to this period.

Then, too, the statistics from Berlin, Paris, and other cities, all coincided in the fact that the mortality from diphtheria since the introduction of antitoxin treatment had been greatly reduced. All of this could not be explained on the basis of coincidence.

Further, it had been repeatedly stated that antitoxin treatment to be of much value must be resorted to within three or four days. As to the Willard Parker Hospital statistics, he had accepted them as they had been given him by the staff. He had personally had nothing to do with making them. They were poorer than those made by the inspectors, included in his report. Regarding cases in the hospital without diphtheria, no cases were taken there which had not at least been reported to the department by physicians as cases of diphtheria and in which the diphtheria bacillus had been found.

So far as his own knowledge extended none had been injected and included in the report as diphtheritic cases on the basis of the presence of diphtheria bacilli without lesion.

Dr. Biggs would like to know from whence came the information that horse serum injected in man dissolved the red blood-corpuscles. It was a new fact in physiology to him.

As to the value of a bacteriological diagnosis of diphtheria, everyone who had had any considerable experience in the treatment of throat affections long before bacteriological examinations had come into vogue agreed that in a certain proportion of cases it was impossible to make the diagnosis of diphtheria; that cases which seemed to be follicular tonsillitis or simple pharyngeal inflammation were sometimes diphtheritic, as shown by subsequent complications. The investigations of the Health Department the last two years had shown repeatedly that persons might have diphtheria bacilli in the throat for a long period of time, that they might infect others long after their own primary attack, and that the latter persons might have virulent diphtheria. These were not questions of opinion, but of absolute demonstration. In a communication made by the Health Department more than a year ago it had been distinctly stated that a considerable proportion of normally healthy people who came in contact with persons with diphtheria had diphtheria bacilli in their throats, and that they might infect other persons and might contract the disease themselves. They had not changed their opinion on that point. But they did not send these cases to the hospital.

Dr. Biggs claimed that Dr. Winters had shown from the beginning of the antitoxin treatment at Willard Parker Hospital profound distrust of the method. In conclusion, he would say that so far as he knew there was not a single distinguished clinician, pathologist, or bacteriologist in Europe who had not accepted the new treatment of diphtheria as the most important advance in therapeutics in modern times.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, March 28, 1895.

H. C. Coe, M.D., Chairman.

Uterus and Vagina in a Case of Sepsis Following Criminal Abortion.—Dr. Simon Marx presented the uterus and vagina of a young woman who had recently died of sepsis following criminal abortion, produced by a

midwife at about the fourth month of pregnancy. He had seen the patient the fifth day, when the question of laparotomy for septic peritonitis arose, but the case had progressed too far to resort to this measure. At the autopsy pus was found everywhere among the intestines, even up to the liver, showing the uselessness of doing laparotomy in acute general septic peritonitis. A point of special interest was the fact that, notwithstanding this condition of sepsis in the abdomen, the uterus and vagina were perfectly clean and contained no detritus. The tubes and ovaries were normal and a corpus luteum of pregnancy was present.

The CHAIRMAN remarked that anatomically it was very difficult to prove criminal abortion.

DR. PRYOR had seen a similar case of abortion at the fourteenth week. The pelvis was perfectly normal, and the woman died of ulcerative endocarditis caused by the streptococcus pyogenes.

Instruments for Vaginal Hysterectomy, etc.—DR. GARCEAU, who was introduced to the Section by Dr. Pryor, exhibited a set of instruments for use in vaginal hysterectomy, etc. Special attention was called to the retractors, made very broad, and giving an amount of room which would seem incredible to one who had not used them.

Malformed Fœtus.—DR. F. H. STUART presented a malformed fœtus, born dead at term, the second pregnancy of a woman of twenty-one, the first child having been normal. The malformation related to the hands, feet, labia, and spina bifida. The feet and hands were turned in, there was webbing, absence of the thumb in one hand, partial thumb in the other, etc. The labia minora were not anchored above, thus bringing down the clitoris. Dr. Stuart said he had never before seen varus of more than two of the extremities, while here it was present in both feet and hands.

DR. GARRIGUES remarked that spina bifida was very often accompanied by other deformities.

The Physiological Effect and General Therapeutic Action of Periodic Induced Currents in Gynecology.—DR. AUGUSTIN H. GOELET read the paper. Periodic induced currents included the faradic or interrupted induced, the alternating, and the static induced currents. The alternating and static induced currents were similar in their action to the faradic current derived from the secondary coil of long wire, being high-tension currents, or currents possessed of a high degree of electromotor force and an almost inappreciable volume or ampèrage. As ordinarily employed, they were currents of high frequency, and in many of the most essential features the effects produced were the same. But they differed widely from the faradic current derived from the secondary coil of short, coarse wire. The latter was a current of much lower E. M. F. and very considerable volume or ampèrage compared with the high-tension currents already mentioned, and its action was entirely different and could not be supplanted by them.

The faradic current could be regarded as practically an interrupted induced current, a current of one direction endowed with polarity, for while it appeared to be alternating through low resistances, yet in the human subject only the break current was felt, being thirteen times stronger in E. M. F. than the make current. That this current exerted an electrolytic action was shown by inserting the electrodes terminating in fine platinum wire into a solution of starch containing some iodide of potassium. The current produced a discoloration at one pole, due to the formation of iodide of starch.

But the electrolytic action was so slight that it might be disregarded except in its effect upon the nerves, diminishing functional activity when passing against the direction of the nerve current, and increasing it when going with the nerve current. In this respect the interrupted induced current possessed an advantage over the alternating, which was being constantly reversed and had no polarity.

The Comparative Average and E. M. F. of the Long and Short Wire.—The stimulating property of the currents depended upon their volume, which in the case of the faradic current could be varied by changing the length and size of the secondary coil, the short, coarse wire having less internal resistance and greater volume, the long, fine wire having greater internal resistance, less volume, but greater E. M. F. The cheaper forms of faradic apparatus were practically worthless, having but one length of wire. The modern induction apparatus was so constructed as to give ten different currents from as many different lengths and three sizes of wire, and afforded great variation in the quality of the current. In this regard it was also superior to the alternating and static induced currents derived from machines as now constructed.

The most noticeable effects of periodic induced currents was a muscle, nerve, and circulatory stimulation. The degree and nature of this stimulation depended upon the E. M. F. and ampèrage and the number of interruptions. In the faradic apparatus the stimulation of the current was governed by the length and size of the wire composing the secondary coil, which regulated the E. M. F. and ampèrage of the secondary current, the force of the primary current being constant or nearly so. The rapidity of the interruptions was controlled by the automatic vibrator in the primary current. The advantage of a number of secondary coils having different lengths of the same wire and different sizes of wire was that the stimulating property of the current might be conveniently and gradually increased as desired.

In the alternating machine now on the market the windings were all the same, hence the stimulating property of the current, which was a secondary, depended upon the strength of the current supplied to the primary fields. The E. M. F. and rapidity of the alternations as well were increased by increasing the speed of the machine, *i.e.*, by increasing the revolutions of the armature or revolving disk. The volume of the current could not be greatly varied.

In the static induced current the size of the Leyden jars regulated the volume of the discharge, and the air-gap between the discharging rods regulated the rapidity of the impulses.

The effect of the short, coarse wire in the faradic machine was to produce muscle stimulation; of the long, fine wire, to produce nerve stimulation. They markedly influenced tissue change. The following explanation was offered: 1. By exciting an increased vermicular contraction of the smaller arteries the blood-pressure was augmented. This caused momentary distention of the capillary vessels, the reaction from which, owing to their elasticity, emptied them into the veins. In case of any obstruction in the capillary vessels this distention, together with blood-pressure, favored its removal. 2. By stimulating contraction of adjacent muscles the veins were emptied and a void was created in their inter-valvular spaces which invited the blood from the overloaded capillaries. Increased activity of the lymphatics was brought about by stimulating absorption and by the contraction of neighboring muscles, hastening the flow of lymph. As a result of this action upon the capillary circulation and lymphatics pelvic congestion was relieved and rapid absorption of exudations was accomplished.

But perhaps the most important effect of periodic induced currents of high E. M. F. and great frequency was the production of sedation and the relief of pain. They acted more especially upon the sensory nerves, and could be made to produce either irritation or sedation. The former when applied in strength sufficient to produce slight irritation, the latter when applied so as to be scarcely perceptible, the current being increased as insensitiveness became apparent. The former, the exciting effect, was desired in pelvic exudation with little sensitiveness; the latter, or sedative

effect, where there was pain and an acute congestion. In the first instance, five or ten minutes' application might suffice, in sedation fifteen or twenty minutes were necessary to produce a satisfactory result. The more rapid the interruptions the more soothing the effect. In using the coarse wire for muscle stimulation the interruptions should be slow, so as to allow alternate contraction and relaxation similar to the normal physiological action of the muscle.

For stimulation three séances a week might be sufficient, for sedation one or more a day were required. As a therapeutic measure for the relief of pelvic pain and congestion, and pelvic inflammations and their results, infiltrations and exudations, this form of electricity was incomparably better than any other agent. It was often absolutely curative, although frequently it served as only an auxiliary to other measures. The coarse-wire current was particularly serviceable where there was loss of muscular tone and venous engorgement, as in subinvolution, but it was contraindicated in sensitive and inflamed conditions.

Dr. Goelet had purposely laid more stress upon periodic currents of high frequency and high E. M. F. because they covered a larger field of usefulness. Hot water, which, under the advocacy of Dr. Emmet, had for so many years been our mainstay in pelvic diseases, sank into insignificance when compared with this current properly used. The trouble was that, like the hot-water vaginal douche itself, the current was so often misapplied.

The Evolution of Hysterectomy in America.—Dr. Ernest W. Cushing, of Boston, read this paper. While the first operations for removal of the uterus were done in this country, yet to no man belonged the exclusive credit of the perfected operation of to-day. It had been a growth, rather than a sudden invention. Burnham, of Lowell, was the first to successfully do hysterectomy, 1853, and was soon followed by Kimball, of the same place, who removed the uterus for a myomatous tumor. Their method of operating was followed for many years, and their results were good when we considered that at this time only the worst cases fell under the knife and antisepsis had not yet been developed. Their mortality was about seventy-five per cent. Burnham performed no more hysterectomies after 1876, and, owing to the fatality of the procedure, only isolated cases were reported for some years subsequently, attention being turned to less radical procedures, such as the use of the cautery, removal of the appendages (Battey, Hegar), injections of ergot. Then came the Schroeder and Marcy improvements upon Kimball's method of treating the stump, Marcy writing in 1881. Dr. Cushing thought Dr. Marcy's method was probably the best one for eight years, or until ligation of the uterine arteries in their continuity was introduced by Stimson. There was no prominent improvement in hysterectomy for ten years prior to 1888, attention having been directed almost entirely to perfecting Schroeder's method of fixing the stump in the abdominal wound.

In February, 1888, Dr. Mary Dixon Jones described a case in which she opened the vagina. When Bantock visited this country in 1887, his method of extra-peritoneal treatment of the stump had reached such a state of perfection that it was resorted to almost exclusively. But in 1889 Dr. Stimson read a paper describing the ligation of the uterine arteries in their continuity, and opening up a procedure which was soon destined to replace the extra-peritoneal method almost entirely. It initiated wide resort to abdominal extirpation of the uterus for various conditions. Eastman, in 1887, had already published his modification of Schroeder's method. In October, 1891, Joseph Price had operated on two cases, opening into the posterior vaginal fornix, modifying and improving Jones's operation, yet he favored Bantock's method and continued to do it with great success to this day. Efforts had not been wanting to get rid of clamps on the stump—Poik, Kelly, Byford. In connection with the intra-peritoneal treatment of the stump the work of A. P. Dudley and J. R. Goffe was referred to, the latter reporting four cases treated by his method in 1890, leaving a cervical stump, covered by peritoneum; but since in all there was a rise of temperature about the fourth day it pointed to lack of drainage, and the cervix had to be dilated. To avoid this danger of infection, some had cauterized the stump and dilated, some had introduced no ligatures into the cervix, others had removed it with the uterus.

About this time, Boldt was using the method of Martin, closing the peritoneum entirely and leaving the vagina open.

In New York, a further development of hysterectomy was made by the introduction of the Trendelenburg position by Dr. Florian Krug. In 1892, Polk read a paper at the meeting of the American Gynecological Society, describing his method of supra-vaginal hysterectomy, which made a very strong impression, and led many to abandon entirely the extra-peritoneal fixation of the stump. At the same meeting, Baer read a paper, describing a treatment of the stump, which Dr. Cushing said was essentially that of the Vienna operator Krobach. The next step related to the application of hysterectomy, Dr. Polk, supported by Dr. Krug, advocating it in 1893 in all cases of disease necessitating entire removal of both tubes and ovaries. There were many, however, who still preferred to leave hysterectomy in such cases for a future operation in the event that it should be required.

At present, the question of choice of route was occupying the attention of the profession, and it seemed that general surgeons inclined toward the abdominal method, while gynecologists had been more impressed with such advantages relating to the vaginal route as avoidance of shock, liability to hernia, etc.

The paper contained statistics of hysterectomy performed in this country and an analysis of the mortality rate by the different methods of operating.

The paper was discussed by Drs. Stimson, Baldy of Philadelphia, Polk, Krug, Rickets of Cincinnati, Goelet, and the author made some concluding remarks.

Dr. Goelet offered the criticism that among palliative measures, scarcely any mention had been made of tying the uterine arteries. There were cases of uterine myoma which had been completely relieved by this procedure, and there were others of the serious type with a pedicle which could be removed without taking away the uterus.

Parisian English.—The Paris correspondent of the *Lancet* writes that, "summoned to attend the child of one of my patients the other day, I found that, alarmed by baby's serious state, a French *confrère* had already been sent for and left directions which a neighboring French druggist had translated for the benefit of the English nurse in charge. The document is too amusing to be passed over, and I therefore make no apology for transcribing it, together with the necessary explanation within parentheses supplied by myself: 1. To distend the children of other children. (To isolate the baby from her sister.) 2. Not many flower in the eat and not give him that milk prepared. (Suppress farinaceous food and also the milk as hitherto prepared.) 3. Before the col of children une éponge warm. (Apply a hot sponge to the child's throat.) 4. Everybody that have occupation of children wild vhach the hands in liquor of van Swieten. (Every person coming in contact with the child to wash his hands in van Swieten's solution.) 5. All the linen deteriored shall be whach in solution before londres. (All soiled linen to be washed in the solution before being sent to the laundress.)"

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL SOCIETY—SIMULATION OF TUBAL GESTATION—GYNECOLOGICAL SOCIETY—DANGER OF MORPHIA IN FEMALE MALADIES—INFLUENZA—QUESTIONS IN PARLIAMENT.

London, March 30, 1895.

On Monday last the subject of tubal gestation was before the Medical Society. Mr. Sutton contrasted a case in which rupture had occurred with one in which the symptoms were simulated by a large uterine myoma with ordinary pregnancy. The diagnosis was so uncertain that delay in interference was decided on, and during the delay abortion occurred. The fœtus was one of about three months. Nine days later serious abdominal symptoms necessitated operation for removing the fibroid, when uninterrupted recovery followed. Cases were mentioned by other Fellows in which tubal gestation had simulated other conditions and *vice versa*. In one Mr. Bidwell bravely related how in breaking down the adhesions formed between the sac and the ileum he had made a rent in the intestine. This he proceeded to resect to the extent of five inches, joining the ends by Maunsell's method. Happily the patient made an excellent recovery, but some criticism was offered on the mishap, and the general opinion seemed to be that it should not be allowed to occur. Mr. Doran thought tubal gestation more frequent than formerly, and said the changes brought about by it differed considerably from those due to inflammation of an ordinary kind. Mr. Cripps said that operation was imperative when hemorrhage took place into the peritoneum, but when into the broad ligament it was wiser to leave it to nature. Dr. Herman said that in cases having a history of reported hemorrhage into the peritoneum it was better to operate at once than to wait until a profuse hemorrhage endangered life. Dr. Lewens had had a case in which twelve months after removal of a gravid tube symptoms of a recurrence in the opposite side occurred. The condition proved to be cystic degeneration of the remaining ovary together with the commencement of normal pregnancy.

The surgical aspects of gynecology have been so prominent that it is quite refreshing to have attention imperatively demanded to the medical side. This has been done by Dr. Macnaughton Jones in a paper on "The Dangers of Morphia in this Department of Practice," read before the British Gynecological Society. Dr. Jones described in a picturesque manner the neurotic women who were likely to become victims to the morphine habit, and showed how great is the danger of prescribing the drug in their cases. The resort to the hypodermic method is the greatest danger of all, and many female morphine maniacs date the commencement of their habit to its use. The responsibility is not, said Dr. Jones, sufficiently recognized in gynecological practice, and he was supported in his conclusion by other speakers. It is to be hoped, therefore, now that a fresh protest has been made, the syringe will be less indiscriminately used. I have many times seen the evil of entrusting this little instrument to the patient or the nurse, and have vigorously protested against this common fault. I am glad, therefore, that Dr. Jones brought up this point, and that others join in the denunciation of a practice which is fraught with danger. Some men denounce chemists for selling morphia, and yet they have themselves instructed patients in its hypodermic use.

Influenza still holds its own as a topic of the day, although it has further declined. The deaths primarily referred to influenza in the last week's returns were 225, of which 37 were persons under twenty and 115 of those over sixty years of age, showing how fatal the disease is in advanced life. Notwithstanding the decline in the deaths, it seems that the severity of the cases is by no means less marked, and doctors are anxious about those which at the onset seem slight. The deaths from the whole class of respiratory disease are still in considerable excess of the average, although there was a fall in the actual weekly number. The Duke of York has had a mild attack of the epidemic, from which the public are assured he is convalescent. Lord Rosebery is overcoming the insomnia which followed his attack. Notabilities of all kinds have been reported as attacked, which is only what might be expected in such an epidemic. Medical men have naturally suffered much and several more victims have fallen.

In Parliament there have been some questions of interest to the profession, though no results are apparent. Thus the imbecile and epileptic children in workhouses, the accommodation for the insane, potato disease, the vaccination commission, substitutes for butter, and pleuro-pneumonia have all been mentioned, but no really definite information has been elicited. Still the mention in the House may be of benefit.

OUR PARIS LETTER.

(From our Special Correspondent.)

INFLUENZA — SERUM "ANTIDIPHTÉRIQUE" IN THE FRENCH ARMY—DISCUSSION ABOUT RHYTHMIC TRACTION OF THE TONGUE IN APPARENT DEATH—PUBLIC HEALTH—CABS AND ASPHYXIA.

Paris, April 1, 1895.

The epidemic of influenza that has prevailed with more or less severity in Paris during the last few months is sensibly diminishing; in fact, the cases, with rare exceptions, have all been of mild type, the usual complications being bronchial catarrh or pneumonia, in which latter the complication assumed an infectious form and rapidly proved fatal. The writer saw one case that was diagnosed as meningitis by several eminent physicians, so exactly did the symptoms represent the group we are accustomed to find in real meningitis. Indeed, influenza is somewhat like hysteria, in that it assumes an almost endless variety of forms—cardiac, bronchial, stomachal, cerebral, renal, intestinal, vesical, and, above all, hepatic. All or any of these usually yield promptly to antipyrine, the great French specific. A little quinine is added, and the strength kept up by wines, spirits, and broths.

The treatment of diphtheritic affections in general by injections into the *flanc* of the now famous horse-serum has reduced the mortality to such an extent as to make deaths from the dread disease quite the exception. Hundreds of thousands of francs have been raised by the *Figaro* and in other ways, so that the serum is now supplied to the poor gratis. This is not only the case in Paris but all over France, and the monetary resources of the Institut Pasteur have recently had such an accession that the Minister of War, in order to assure the treatment of diphtheritic affections in the active army by sérothérapie, and to facilitate the application of that method in all garrison centres, has just decided to have placed in the sanitary service of each army corps a supply of the serum and syringes of a special model—that used at the Institut Pasteur.

Laborde's method of resuscitation in cases of apparent death by drowning and in apparent death of the new-born, has raised considerable discussion, being mainly opposed by Professor Pinard, of the Baudelocque Lying-in Hospital, who has tried it in his wards and finds it vastly inferior to resuscitation by insufflation. He is willing to admit that rhythmic tractions on the tongue are of great efficacy when it is a question of adults, and more especially with apparent death by drowning. Insufflation by Ribemont's tube was practised upon 17 infants; and, although 11 of them died,

respiration was nevertheless re-established; in the 6 other cases the combined methods were used, that is, insufflation and rhythmic tractions on the tongue. Caution is necessary not to rupture the air-sacs of the lung by too brisk insufflation.

The last *Bulletin Hebdomadaire de Statistique Municipale* reports the number of deaths in Paris somewhat below the average for March. Especially noteworthy is the extremely low rate from typhoid fever, there having been only two deaths during the last week instead of twenty-two, the average. This is due to the excellent drinking-water with which the city is now provided.

Although the spring days are come, yet the cab companies still continue with their chaufferettes filled with charcoal; consequently there have been several cases of partial asphyxia from this cause, characterized by a sense of tightness around the head, flushed countenance, often violent headache with inability to move, dulness of reflex, and altogether a state that recalls lethargy and is the beginning of real mortal asphyxia. Fortunately the persons were found at the end of the drives, which are generally not very long, and no actual deaths have as yet occurred.

CASTRATION FOR ENLARGED PROSTATE.

To the Editor of the Medical Record.

Sir: The letter by Dr. L. Bolton Bangs which appears in your issue of April 6th has much interested me and has decided me to publish at once the following case, which shows improvement so remarkable as to be practically a cure, following castration for enlarged prostate. The case is one which has been carefully watched, both before and after operation, by at least three observers who may be considered competent. There was no lack of attempt at palliation by the usual methods before resort to the castration.

M. M——, a private patient in Mt. Sinai Hospital in Dr. Gerster's service, was fifty-six years of age, and the father of a family. He was a merchant by occupation and lived in one of the Southern States. For about ten years he had been troubled with frequent micturition, with occasional attacks of vesical tenesmus, and with a gradual increase in the severity of his symptoms. About three years before coming to the hospital he had been catheterized for an attack of retention, but the exacerbation was of short duration. Still, from this time he had to be catheterized with gradually increasing frequency until, on admission to Mt. Sinai, he was in constant pain and felt an urgent desire to urinate at least once an hour during the night. By day his condition was much worse, the attempts at emptying the bladder occurring about every five to fifteen minutes. His urine was alkaline, and there was a severe cystitis, with great quantities of pus and bloody mucus. A full-sized sound entered the bladder without difficulty. Dr. Gerster examined the prostate by rectum, and found it enlarged to about three times the normal size, but the cystoscope showed a well-marked middle lobe, which was thought to be responsible for the trouble in evacuating the bladder. For six weeks the patient was treated by catheterization, washings of the bladder, diuretics, oil of wintergreen, and other internal antiseptics, but without improvement. Indeed, the man grew constantly worse. He was now emaciated, was thoroughly exhausted and in a truly desperate condition. Dr. Gerster had proposed castration, but the patient had refused. The service now changed and I came on duty. At my first examination of the prostate by rectum I found the body about as big as a good-sized egg, not particularly tender to touch, but very firm and resisting. I made no cystoscopic examination, but accepted the positive observation of Dr. Gerster. When castration was again proposed the patient had become so hopeless that he decided to take his chances with the operation. At my request Dr. Fluhrer saw Mr. M—— and examined him. He also diagnosed the case as one of enlarged prostate, and on learning that the treatment above outlined had been followed by no improvement whatever in six weeks he agreed with me as to the advisability of castration.

On February 9th, under chloroform anesthesia, I removed both testicles, which were nearly normal. There were signs of very slight bilateral epididymitis. The wounds were closed without drainage and the patient was out of bed in six days. The patient was catheterized every six hours, and his bladder was washed twice daily. For the first twenty-four hours there was a slight remission of symptoms, but on the third day he was almost as bad as ever. From the fifth day there was, however, steady and miraculously rapid improvement. Before the operation and immediately after, he could urinate only by drops, and there was always four to six ounces of residual urine. If he had allowed his bladder to become distended practically all the urine was "residual," so that frequently at such times, after the man had exhausted himself trying to pass his water, ten ounces were withdrawn by catheter. The first improvement noted was that patient could pass a stream. The residual urine rapidly diminished, the cystitis vanished, and in four weeks I presented him at a meeting of the Genito-urinary Section of the New York Academy of Medicine. At that time he could hold his urine two hours at a time without discomfort, he passed a moderately powerful and full stream, and best of all there was but one ounce of residual urine. The urine still contained some pus but no mucus. It was acid and of the normal odor. The man had gained many pounds in weight and enjoyed life. He could go to the theatre and could make the journey to Brooklyn, where he had relatives, without suffering by the way. It is needless to say that he is most grateful for what has been done for him. He does not for an instant mourn the loss of his testicles.

No cystoscopic examination was made after the operation, but by the rectum the prostate, though still enlarged, is only about half the size it was before and feels flaccid.

Both Dr. Gerster and Dr. Fluhrer have seen Mr. M——since his recovery, and express themselves as thoroughly convinced of the efficacy of the operation in this case.

A few days ago the patient returned to his home. Before leaving he again came to thank me and to say that catheterization was no longer necessary, the amount of residual urine being so small. I still advised the use of the instrument, however, once in two days, until there should be no residual urine.

Howard Lilienthal, M.D.

33 East Thirty-first Street, April 7, 1895.

A MEDICAL FRAUD.

To the Editor of the Medical Record.

Sir: I wish to call attention to a clever scoundrel who is collecting subscriptions for himself and family on the supposed recommendation of Dr. Howard A. Kelly, of Baltimore. The letter which he presents is a forgery, as Dr. Kelly informs me by telegraph. Appended to the letter are several subscriptions from prominent members of our profession in this city. His story is that he left Birmingham, England, three years ago, and settled in Baltimore, to practise abdominal surgery there. He claims to be an intimate friend of Lawson Tait, with whom he says he is in frequent correspondence; in fact had a letter from him only a few days ago, in which Tait advises him to return to England, and promises him work again in Birmingham. He had failed to obtain the success in Baltimore that he had good reason to expect, and now asks for a little help to enable him to return

to England. Dr. Kelly's forged letter recommends him warmly as worthy of assistance. When I asked him if it had not occurred to him that coming from England to practise abdominal surgery in this country was very much like carrying coals to Newcastle, he modestly replied that I was quite right; he had made a mistake, and has been misled by American medical tourists, who had given him glowing accounts of the success of abdominal surgery in this country. The man was shabbily dressed, redolent of whiskey and tobacco, and was evidently a medical tramp on a rapid descent to Avernus. If any one of your readers to whom he presents his forged letter will retain possession of it, send for a policeman at once, and then notify me, Dr. Kelly and I will see that he gets his punishment.

42 West Thirty-sixth Street.

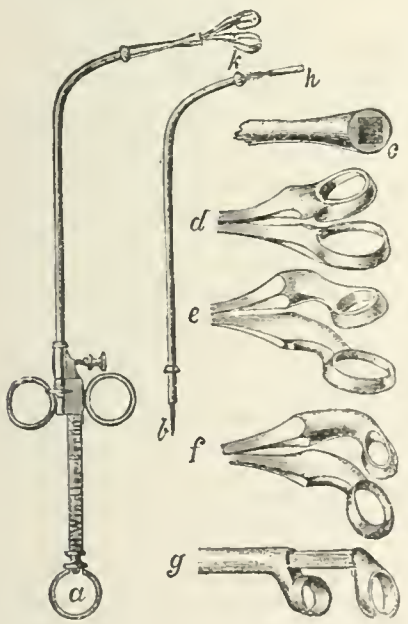
New Instruments.

SURGICAL TREATMENT OF TUBERCULAR LARYNGITIS.[1]

By C. P. AMBLER, M.D.,
Canton, Ohio.
Formerly Laryngologist and Rhinologist to Wingate Sanitarium, Asheville, N. C.

The removal of a circumscribed tubercular deposit from any part of the body by surgical means has for years been recognized as a rational procedure. The frequency with which the deposit involves organs beyond the domain of surgery as we practise it to-day has alone restricted our operative measures.

Following the discovery of the laryngoscope, it remained for Heryng and Krause to construct and perfect an instrument which opened up a new field in the treatment of tubercular laryngitis.



Double Rotary Curette of Heryng; *a*, instrument complete ready for use; *b*, cannulated shaft; *k*, thumb screw; *c*, rectangular socket; *d*, *e*, *f*, double curettes to fit in rectangular socket *c*. The rectangular socket prevents the knives *d*, *e*, *f*, from twisting when in use, and by rotating *c* on the cannula the knife can be set at any desired angle; *g*, punch for ventricular band.

They were among the first to employ the sharp curette proper in the larynx; succeeding with this, they realized that a cutting instrument, with broader scope, more powerful, and retaining the safety features of the first curette, would be of immense value. In their double cutting instrument they have the adaptability, and the power is applied in so ingenious a method that the danger from using a cutting instrument in the larynx is reduced to the minimum, while the compact arrangement of the tool admits of its delicate application and manipulation without materially interfering with vision.

Upon publishing their report the method was received with doubt by the profession generally; many criticisms were made, and while time has changed all this in Europe, where the most brilliant results are being accomplished, here in America but very little has been attempted in this direction.

On October 25, 1894, Dr. J. W. Gleitsman, of New York, who has probably had more experience with these instruments than any other surgeon in America, read a paper upon this subject before the New York Academy of Medicine (Laryngological Section), and even here the members were almost unable to discuss his paper except from a theoretical standpoint. "The chairman, Dr. Delavan, expressed the opinion that this subject of the surgical treatment of laryngeal tuberculosis ought to be better understood in this country. He also stated that the work done in Berlin was far in advance of anything we have any idea of here."

When the methods of Heryng and Krause were first made public the arguments used against such means were:

1. That the wound left after the removal of such tissue as could be reached, would in itself become a tubercular ulcer with no tendency to heal.

2. That the open wound would be a new source for infection, increasing the danger of auto-infection.

3. That the instruments were not practicable in application on account of the inability of the patient to control the throat.

4. That the wound would increase cough and secretion.

5. That the hemorrhage would be severe and beyond control.

6. That it was a question if such instruments could be applied to the intra- or sublaryngeal cavity with precision.

The first objection seems plausible, but facts contradict it. The wound heals more readily than would be expected, and in fact the double-cutting as well as the single curette is applied to open ulcers, the wound healing, where no drug application would stimulate the process of repair.

2. To the second objection we can only say that it is exceedingly rare that the laryngeal deposit is primary, pulmonary involvement generally preceding it and the small wound would be trivial in comparison to other open surfaces.

3. With cocaine, patience on the part of the operator, frequent and systematic manipulation carried out for weeks if necessary, the throat can invariably be brought to toleration.

4. The wound does increase both secretion and cough primarily, but the ultimate result is a marked decrease.

5. Remembering the anatomy, the danger from hæmorrhage is slight. Following each curettement a sixty per cent. solution of conlactic acid is rubbed into the wound. If one application of this does not control the bleeding the parts are similarly treated with a mixture of equal parts liquor ferri and eighty per cent. lactic acid.

6. The last objection requires no answer. The work that has been accomplished speaks for itself.

As laryngologist to Wingate Sanitarium, Asheville, N. C., I had the pleasure to report one of the first successful operations of this kind made in this country. A report of this case was made in the *Therapeutic Gazette*, May 15, 1891. In this case the larynx was almost entirely closed with the tubercular deposit and its concomitant conditions, both arytenoids and false bands were especially enlarged, the vocal cords could not be seen. When admitted she was wearing a trache-

[1] Read before the Stark County Academy of Medicine March 5, 1895.

otomy tube, the same having been put in by Dr. Gerster, in New York City.

While the tube was in position the double-cutting curette was applied, in all at nine different sittings at intervals of a few days, and later a week apart. The result was so successful that she not only became able to breathe and cough naturally, but also regained the use of her voice, having been aphonic for eighteen months. The tracheotomy tube was dispensed with, and while she died a year and a half later from pulmonary trouble, she could never find words to express her gratitude for the relief and comfort the operation gave her.

Following this case the curettes, especially the double-cutting punches were applied in many cases and never with any untoward effect. The instruments used then were the old pattern, and were lost in a fire which occurred in August, 1892. Having since imported a set from Berlin through Meyrowitz, of New York, I present them to you to-day.

These are Krause's latest instruments and consist, as you see, of two forceps for removal of foreign bodies from the larynx, of the double antero-posterior and lateral punch, of two smaller straight double punches, a Sajous's snare for either larynx or nose, and the double rotary curette of Heryng. The chief advantage of the last instrument is that while attached to a common stem, it can be turned in different directions.

A glance at the instrument plainly shows the vast improvement that has been made in recent years in the manufacture of instruments for intra-laryngeal operations. The double-cutting instrument is spoken of as a curette, it simply being a modification of the sharp curette first used; this, however, is a misleading name, it should be called a punch, to distinguish it from the former, which requires a scraping movement in its application. If one is thoroughly accustomed to the use of the laryngoscope, there is no especial difficulty in the application of such instruments. The power to unconsciously transpose the laryngeal image, to reverse the image as it were, to keep the image in perfect view, together with the skill to control your instrument under the mirror, constitute the main difficulties. This, of course, can only be acquired by long and continued practice, and holds true for all laryngeal work, even the most simple applications.

It is to be hoped that the toxin method of treating germ diseases will enable us before long to combat tuberculosis more successfully, but should our greatest expectations be realized, there will be conditions met with requiring operative interference on account of threatened stenosis, and in this class of cases the laryngeal punch will be used more than ever.

Whether with or without antiphthisine treatment the laryngeal punch will still be an aid in giving relief, at least. It is a valuable addition to our armamentarium in treating this to-day practicably incurable disease and deserves to be better known and more extensively used.

NEW EYE FIXATION FORCEPS.

By H. E. HOLMES, M.D.,

Minneapolis, Minn.

Any one who has ever made a corneal section with the ordinary single fixation forceps, must have been, at times, annoyed by the rotary movements of the globe around the fixed point as a centre, making it almost impossible to obtain a clean-cut wound, and at the same time allowing the cornea to assume an elliptical shape as the aqueous escapes, and increasing the danger of the iris falling before the knife. To obviate this, and to insure a perfect fixation of the eyeball at two points exactly opposite the cutting portions of the knife, I have had made by Messrs. George Tiemann & Co., a pair of double forceps which are represented in the accompanying cut. The extremities of the blades are placed at an angle so as to form a tangent with the average globe, and the distance between them is that of the width of the average cornea, or a little less—about eleven milli-

meters. In ordinary cataract operations they should be fixed parallel with the horizontal diameter of the cornea and a few millimeters below; the eyeball is then firmly fixed without pressure or traction, and can be instantly released if necessary.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 13, 1895.

	Cases.	Deaths.
Typhoid fever	6	3
Scarlet fever	105	11
Cerebro-spinal meningitis	1	7
Measles	202	11
Diphtheria	228	34
Small-pox	4	0

Child Mortality in England.—From a recent editorial in the *Lancet* we learn that the Registrar-General's death-rates show that the annual death-rate among children aged under five years in England and Wales, which was 68.6 per 1,000 in 1861–70, declined successively to 63.5 and 56.8 in 1871–80 and 1881–90. From these figures it is evident, as we recently pointed out, that in 1871–80 the mean rate of child mortality was 7.4 per cent. lower than it had been in 1861–70, while in the decade 1881–90 a further decline of 10.6 per cent. took place. Thus it is conclusively proved that the true incidence of mortality at the age-group 0 to 5 declined during the thirty years 1861–90 at an increasing rate of decrease. So much for the facts. How, then, does Mr. Biddle arrive at his "coefficients," which show increased incidence of child mortality? It must be freely admitted that the rate of decrease of child mortality during this period of thirty years has not been equal to the rate of decrease of mortality at the later age-periods. It follows, therefore, that child mortality, compared with adult mortality, is relatively higher, although actually lower, now, than it was before the marked decline in our national death-rate set in. Mr. Biddle, therefore, divides the annual death-rate of children under five years of age by the annual death-rate at all ages, and calls the result or quotient the "coefficient of incidence." We have objected to this term because it conveys no definite idea of its construction or meaning; and still more because the method of its production necessarily destroys, as we shall see, its value as a test of the real incidence of mortality. Mr. Biddle's "coefficients" really only represent the relative proportion that the rate of mortality at any given age-group bears to the rate of mortality at all ages. Therefore, as we know from the Registrar-General's death-rates that adult mortality has in recent years declined far more than child mortality, the so-called "coefficient" of child mortality has necessarily increased, notwithstanding the actual decline in the true rate of mortality. In order to prove the fallacy involved in the attempt to use the "coefficient" as a test of the incidence of mortality, we need only note Mr. Biddle's admission that his "coefficient" of child mortality has shown a tendency to steadily increase un-

less "an exceptional visitation, such as influenza, affects the other groups." Thus, the "coefficient" method involves the absurdity that an increased mortality from influenza, or any adult disease, invites the assumption of an increased "power of resistance to disease and death" among children; whereas, the beneficent discovery of a prophylactic for phthisis or cancer would, on the other hand, apparently justify his most gloomy conclusions as to the supposed decrease of the "power of resistance" in the age-group 0 to 5. Mr. Biddle, we feel sure, would admit that there would be nothing "hideously wrong" in an increase of his "coefficient of incidence" of child mortality due to the extinction of phthisis or cancer. It may, moreover, be interesting to him to know that, if the present excessive rate of mortality among children under the age of five years could be reduced to a third of its present figure, the "coefficient" for this age-period would scarcely indicate this startling decrease of child mortality, as he suggests, because the death-rate at all ages would thereby be necessarily reduced to a marked extent. It is needless, as it is impossible, here to discuss what the death-rate of childhood ought to be, certainly much lower than it is; but it would be sheer optimism to expect that it should not exceed the mean rate of all ages. Neither need we feel either surprise or despair that sanitary effort has influenced it less than the death-rate at later age-groups. It is well to bear in mind, however, that while, according to the latest published English Life Table for England and Wales (1876–80), the mean rate of mortality under five years was 61.0 per 1,000, the rate according to Dr. Farr's Healthy District Life Table was only 39.4, and according to Ansell's Table, based upon upper-class experience, did not exceed 28.2. Child mortality in England and Wales, judged by the Registrar-General's statistics for a long series of years, is decidedly decreasing, but we do not hesitate to agree with Mr. Biddle that there is "something hideously wrong" in the still terribly excessive waste of child life in this country.

Titles of Some Old French Theses.—The following are a few theses, authentically titled, that will serve to give some idea of the curious thoughts of former Parisian medical students:

"Does the fœtus resemble the father more than the mother?" (1376.)

"Is water more healthy than wine?" (1622.)

"Does the worship of Venus drive away disease?" (Affirmative.)

François Le Sage: "An mulieri preferatæ vir succulentus?" (1612.)

Dennis Joucquet: "An aurora veneris amica?" (1637.)

Robert Debonnaire: "Are infants born with a caul the happier?" (1637.)

Andre Guget: "Are heroes not born at the tenth month?" (1643.)

Hippolite Duval: "A nex salacitate calvities?" (1662.)

"Is music efficacious in disease?" (1624.)

"Should a young girl in love be bled?" (1639.)

"Is getting drunk once a month healthful?" (1643.)

"Is woman an imperfect work of nature?" (1646.)

"Does libertinage induce baldness?" (1662.)

"Should literary men marry?" (1745.)

—*Cincinnati Lancet-Clinic.*

The Boiling-point of Milk.—Dr. Edmunds, writing in the *British Medical Journal*, makes the following observations on this subject: Referring to the temperature at which typhoid bacilli are killed, a correspondent assumes that milk boils at 180° to 190° F. This is a mistake which needs correction. Milk boils at a temperature higher than that of water, and it is well known that boiling milk inflicts a much more serious scald than boiling water. The point at which milk boils will vary half a degree or more, according to the amount of its saline and other non-aqueous constituents, but I find that a fair sample of milk, taken from my own kitchen, boils at 213.5° F. when tested with a standard chemical thermometer. I have always advised that milk boiled for one minute is made safe by the killing of any infective germs which it might have contained. The butter contained in the milk does not seem to raise its boiling-point, but it is well known that butter and other fats and fixed oils boil at a very much higher temperature, and that boiling fixed oils destroy the skin as effectually as melted lead. In the manufacture of tin plate—that is, sheet iron plated with tin—the tin is kept melted under melted tallow, and the clean sheet iron is tinned by being passed through this bath of molten tin. Fixed oils may be heated to about 500° F. without undergoing material change, but at about 600° F. they begin to boil, owing to the evolution of gases, which are set free as a process of destructive distillation. It is generally held that the typhoid infection of milk is due to contaminated water used for washing the milk vessels or for augmenting the bulk of the milk by fraudulent additions. My own opinion is that an escape of fecal matter from the cow while being milked often falls into the milk-pail, and that this is generally the real cause of typhoid infection in milk. I have actually seen this to occur when inspecting dairies and examining suspected cows, and I am perfectly sure that it often takes place. The polluted-water theory seems to me to be far-fetched and inadequate.

A Pocket Explosion.—On the morning of Saturday, January 19th, Dr. Davidson was called to see a patient and found him suffering from an extensive burn of the inner surface of the left thigh, with another burn of smaller extent, but more severe, extending over the thenar half of the left palm. The history of the injury elicited was that the patient had been suffering from sore throat and had purchased some chlorate of potash lozenges. These he was carrying in his trousers pocket rolled up in a piece of paper. One of the lozenges was loose in the pocket, which also contained a box of safety matches. While moving about he suddenly heard a noise like the hissing of a squib before the detonation, and saw smoke issuing from his pocket, which he grasped from the outside thinking to smother the fire. An explosion followed which blew out the whole of the front of the trousers leg. There was no loud noise, only an exaggeration of the hissing noise heard at first, but there was a considerable volume of flame. What had evidently happened was that the loose lozenge, by rubbing on the composition on the outside of the box of safety matches, had become ignited, and that the rest of the lozenges had been exploded by it, causing the chief explosion. On the room being searched the remains of several of the lozenges were found. They had been reduced to about a third of their normal size and the outside of them appeared scorched. The patient had fully one ounce of the lozenges in his pocket at the time of the occurrence. On January 25th the wounds were healing rapidly and were almost entirely covered with new epidermis.—*The Lancet*, February 16, 1895.

The Influence of Climate on Health and Disease.—Mr. Harrington, chief of the Weather Bureau of the United States Department of Agriculture, has issued the following circular: "The interest manifested by every class of people in the subject of climate and its influence on health and disease, has determined the Honorable the Secretary of Agriculture, through the medium of the Weather Bureau, to undertake the systematic investigation of the subject. It is hoped to make the proposed investigation of interest and value to all, but especially to the medical and sanitary professions, and to the large number of persons who seek, by visitation of health-resorts and change of climate, either to restore health or prolong lives incurably af-

fected or to ward off threatened disease. The study of the climate of the country in connection with the indigenous diseases should be of material service to every community, in showing to what degree local climatic peculiarities may favor or combat the development of the different diseases, and by suggesting, in many instances, supplementary sanitary precautions; also by indicating to what parts of the country invalids and health seekers may be sent to find climatic surroundings best adapted to the alleviation or cure of their particular cases. The hearty co-operation of the various boards of health, public sanitary authorities, sanitary associations and societies, and of physicians who may feel an interest in the work, is asked to achieve and perfect the aims of this investigation. No compensation can be offered for this co-operation other than to send, free of cost, the publications of the Bureau bearing upon climatology and its relation to health and disease to all those who assist in the work. Co-operation will consist in sending to this office reports of vital statistics from the various localities. That these reports may be of value, it is evident to all that they should be accurate and complete, and be rendered promptly and regularly. Blank forms of reports have been prepared so as to occasion as little trouble and labor as possible on the part of the reporter, and will be furnished by the Bureau on application. At the very beginning of the investigation it is not possible to outline precisely the channels through which the results obtained will be made public, but it is hoped to publish soon a periodical devoted to climatology and its relations to health and disease. The publication will probably resemble in size and general appearance the present *Monthly Weather Review*, the subject matter being, of course, different. More detailed information will be furnished on application."

An Unusual Obstetric Experience.—Dr. E. G. Roberts, of Fair Haven, Vt., writes: "From a Welsh newspaper of recent date I translate the following account of an unusual occurrence, which took place during the late severe weather near Rhosmarket, Pembrokeshire, Wales. A young married woman left her home in the parish of Burton with the intention of walking to her mother's house in Rhosmarket—a distance of about four miles—where she intended to stay until a certain expected event should take place. Her mother walked halfway to meet her, and was thunderstruck to see her carrying a newly born babe in her arms. The mother and child were taken to the nearest house as quickly as possible, where another child was born shortly after. This happened in the severest weather with deep snow covering the ground. The paper does not state whether the mother or children suffered from their hard experience, but from its silence it may be inferred that the case did well."

The Lady and the Dog.—We recently published the letter of a female anti-vivisector who refused the use of a dog (from the Philadelphia pound) in carrying out a surgical procedure proposed by Dr. W. W. Keen. The answer of Dr. Keen to the lady much deserves publication also. He says: "Aside from myself there are three parties who are to be considered in this matter. First, the dog; second, the man, and third, mankind. First, the dog; I stated to you that the dog would not suffer; that he would be treated with the same care as the man, and that after the operation I should continue the anæsthetic until the dog was dead. Yet you refuse me the dog because, forsooth, somebody else may be cruel to some other dog. Secondly, the man. This man knows what I am going to do, and is anxious to have it done. His leg is paralyzed. If by an ordinary surgical procedure I can re-establish the continuity of the nerve, I may be able to cure his paralysis. In that case I should not have recourse to the dog. If, on the contrary, the gap between the two ends of the nerve is so great that I cannot bring them together, either the man must be condemned to paralysis for life or some other means must be tried to re-establish the nerve and so restore to him a useful leg. This might be done by the process of nerve-grafting. Yet you refuse me a dog on the ground that it is an 'experiment.' Granting that it is, it is at the most a perfectly harmless experiment, for it would not be more painful than any ordinary operation; and even if it absolutely fails, it leaves the patient not a whit the worse off. If it succeeds, it will be the greatest possible service to him. Thirdly, mankind. The only way in which surgery can make any progress is by testing new methods of treatment which have at least a reasonable possibility of success. Just such persistence and continued trials have encircled the globe with ocean cables. But you assume the *rôle* of a judge, who decides that such a new method of treatment shall not be tested. You, who I presume would admit that you know nothing of surgery, put your judgment against that of one who has spent thirty-five years in the earnest study, active practice, and continuous teaching of surgery. You will excuse me if I think you are not a competent judge. If you had your way there would be no Pasteur Institutes in any part of the world to save so many lives from hydrophobia; there would be no antitoxin treatment of diphtheria, which already has borne such wonderful results; there would be no inoculation against cholera, which in the hands of Haffkine bids fair to rescue thousands of lives; there would be no cerebral surgery, since you would not allow us to investigate the functions of the brain; there would be little or no antiseptic surgery, the greatest stride forward of this century. In your misguided zeal for dogs you are guilty, in my opinion, of cruelty to this man, and cruelty to all mankind, because you thwart scientific progress under the guise of love for animals. You would condemn to the torture and disabilities of accident and disease, people who have happily been rescued by the more humane scientists in my profession. You will pardon me if I write earnestly. It is because I feel deeply the injury you are trying to inflict upon the human race. Happily, the common sense of the community does not allow you to have your way, as they prefer the devotion of my own profession to the welfare of mankind, to your devotion to dogs in preference to men."

ILLUSTRATIVE CASES OF CALCULOUS DISEASE.[1]

BY L. BOLTON BANGS, M.D.,

NEW YORK.

CONSULTING SURGEON TO ST. LUKE'S, CITY, AND METHODIST EPISCOPAL HOSPITALS, ETC.

ALTHOUGH I have nothing very new to present to you, some interesting deductions may be made, and perhaps some clinical advantages derived, from a brief study of the following cases:

The first case to be narrated shows that a stone of medium size may remain in the bladder for an indefinite time, without giving rise to serious symptoms, providing proper care be taken of the individual. The patient was a man who died about seven years ago at the age of seventy-four. He had been under my care more or less constantly for the previous eight years. He was a gentleman of means, who had never been robust, who had many ideas in regard to his health, and had passed through the various stages of vegetarianism, clairvoyance, and homœopathy, and had finally become a valetudinarian, but tolerably docile under my directions. During the whole time that he was under my care he had the usual symptoms, subjective and objective, of prostatic hypertrophy, with a very mild grade of vesical catarrh, and had been unable to pass a drop of urine spontaneously. At times he had symptoms which were suggestive to me of stone; but I was able to make him so comfortable by frequent ablution of the bladder and quiet in bed that he always positively refused any instrumentation, even so simple as exploration of the bladder. He had a body-servant, had extra springs put on his carriage, never walked, excepting about his rooms, and his exercise in the open air consisted of a daily prolonged drive. This went on year after year, with occasional intercurrent attacks of nephritis, until his final sickness, which was also an attack of acute nephritis terminating in uræmic coma and death. He had two great fears: one was pain, and the other lest he should be buried alive. For several years on returning to my care in each autumn, he made me promise, firstly, that I would see to it that he should have no pain; and secondly, that after his final sickness I would make certain that he was dead. Accordingly, after his death, I informed the relatives that my part of the agreement was to be carried out; and that one of the most certain ways of determining positive death was to make an incision into him. This I did by opening the bladder, and found, as I had anticipated, this stone which I now show you, which weighs 123 grains and measures $1 \times \frac{7}{8} \times \frac{6}{8}$ inch. I have no doubt that he had stone in his bladder for at least three years prior to his death, but he was so content with his condition, and was so delicate, together with the chronically advancing condition of his kidneys that I also was content to let well enough alone.

In this case the symptom which was suggestive of stone was pain, induced or aggravated by jolting and sudden stoppage of the stream of urine as it flowed from the catheter. Ordinarily, in the subacute or chronic condition of prostatics, especially after the establishment of catheter life, pain is not experienced unless an acute inflammatory attack supervenes. But if pain be persistent, and aggravated at the end of the act of urination, or by motion, and associated with sharp spasms, stone may be suspected. If there also be frequency of urination, other than the habit of the individual, together with sudden stoppage of urine in full stream (even when the catheter is used), and the appearance of blood in the urine, stone should be searched for. Priapism and reflex pains are also suggestive.

A few years ago I was summoned to see a man, over sixty years of age, who had been in fairly good health, but for several years had suffered from some indefinite bladder trouble, which a few weeks prior to my visit had become positive and severe in character. He was under medical care, but his symptoms becoming serious I was summoned. He was then in very poor condition, with a weak and rapid pulse. He was urinating every few minutes, with violent tenesmus, and it seemed to me that his condition was extremely critical. Searching of the bladder immediately revealed a large calculus, and I proposed that an operation for its removal should be done on the following day; in the meantime, bracing him up with tonics and stimulants, with frequent ablution of the bladder. On the following morning, to my great astonishment, I received word that because it was Friday he positively refused to be operated on. My surprise was increased by the fact that the man was an Israelite, for I did not know that that race had any particular superstition about Friday. On the following day (Saturday) word was sent me that his condition having become desperate, he had been hurried out to a hospital, where he immediately died. Through the courtesy of the house staff of the hospital I am able to present to you a cast of the stone, which was removed from his bladder post mortem. It measures $2\frac{3}{8} \times 1\frac{7}{8} \times 1\frac{1}{2}$ inches (circumferences = $6\frac{1}{8}$ and $5\frac{3}{8}$ inches).

Unfortunately, this man's history, as regards the commencement of calculous symptoms, is very indefinite, but it is certain he had bladder symptoms extending over several years, during which a stone may have formed insidiously, and then increased very rapidly in size during the latter part of his life. A stone may form in the bladder, primarily, very slowly; or, a gravel which has descended from the kidney may lie dormant for an indefinite period, and suddenly, because of some change in the condition of the bladder or in the constituents of the urine, have a very rapid accession to its size.

Stone may be present without giving rise to any symptoms calling attention to the bladder or the genito-urinary organs. For example, a gentleman, aged fifty, of a rheumatic or lithæmic tendency, but who had always been well with the exception of occasional attacks of migraine and muscular pains, was subjected to a prolonged business strain by which he was extremely prostrated and finally confined to his bed for a week with no other symptoms than those of neurasthenia. He had no symptom whatever pointing to the bladder—no pain, no frequency of urination. On the fifth day of his confinement to bed he got up to urinate and passed, with slight scalding, a calculus, irregularly oblong in shape, which he brought to me. It

[1] Read at a meeting of The Practitioners' Society, Newark, N. J., April 1, 1895.

weighed less than one-quarter of a grain (.215) and was composed chiefly of oxalate of lime, with smaller proportions of phosphate of calcium, of ammonium and magnesium and fibrin, and a small amount of that rare substance, xanthine. The passage of the stone was a great surprise to him, and he could scarcely believe that he had emitted it. Since then he has been perfectly well, with the exception that occasionally he rises to urinate once at night and at times (rarely), has urine of high specific gravity, which scalds him slightly as it is passed. How long was this little calculus in forming and where did it originate? in the bladder or a kidney?

In the spring of 1892 a young man, aged thirty-three, was sent to me from the interior of the State. He was suffering constantly and so weak that he could hardly walk. The following is a brief synopsis of his history: He had passed gravel from his urethra since he was seven years of age and had never been robust, although able to work. Seven years before I saw him he had married, and his wife had borne him children, the youngest being eight months old. He had had occasional attacks of what were called "kidney and bladder disease," which he said consisted of pain in the groin and over the pubes, with frequent and painful urination. About a year after his marriage, that is to say, six years before he came to see me, he was said to have "inflammation of the bladder," and a physician introduced into his urethra a sound with such violence as to cause intense pain, and the same night the patient passed a "chamberful" of clotted blood. Since then he has had to urinate every hour on the average, and sometimes as often as five times in one hour. Pain was always present at the end of the act of urination, the latter being accompanied by violent straining. He was obliged to sit down in order to urinate voluntarily, and for the past two weeks he has been compelled to empty the bladder with a catheter. At the time of my examination he passed about half an ounce of thick, bloody, foul urine, which was declared to be the usual quantity passed at each act. He groaned with pain immediately after its expulsion. Pressure upon the base of the bladder and prostate forced out a gush of thick, grumous, foul-smelling pus from the urethra. The searcher revealed a calculus, but its size and character could not be made out because of the extreme sensitiveness of the bladder. He was put to bed and his bladder was frequently irrigated for one week. He was then etherized and a careful attempt made to seize and crush the stone, but this was found to be impossible. The bladder would hold but little fluid. The lithotrite seemed to ride over a large mass of stone, and its beak could not be turned down toward the calculus. I accordingly desisted; introduced a sound, which was turned up behind the pubes, and upon the point of this as a guide did a suprapubic cystotomy. Through the incisions the exploring finger very readily made out a large calculus, which was immovable in the bladder. It projected upward and backward into the cavity of the bladder, and further exploration showed that a large part of its longest diameter was embedded in the base of the bladder, which surrounded and adhered to it. Before it could be removed I had to enucleate it by putting two fingers of the other hand into the rectum, thus making counter-pressure, and with two fingers of the hand in the suprapubic opening I pushed away the tissues which surrounded it. I now show you this calculus, which weighs 607 grains. It is shaped somewhat like an egg, and has the general appearance of a phosphatic stone. This man made a rapid and good recovery, and was allowed to go to his country home before the suprapubic sinus was healed, instructions being given to his doctor how to treat the diseased bladder.

In all cases of vesical calculus the bladder requires after-treatment; otherwise there may be relapses of stone formation, and a return to the patient's previous condition. Unfortunately, the relief to these patients is so great that they either do not seek the advice and assistance of their physician, or else the latter, knowing that the stone has been removed, does not feel the necessity for further treatment of the patient. This case is a good illustration of these points. The patient returned to his home in June; the following November he came to me again, urinating every few minutes, with the suprapubic sinus still open, and although he declared that he had washed his bladder every day, he was still passing stinking, ammoniacal urine. He was washed out thoroughly and the sinus rendered aseptic. Then the bladder and sinus were washed with a solution of silver nitrate, and he was instructed how to wash his bladder with boiled water containing boracic acid, and told to go to work, which he stated he had been afraid to do, lest he "should break open." The sinus healed in four days, and six months later he wrote to me stating that he was entirely well. I present this case to you in order to show how this individual had been neglected or imperfectly treated from his childhood up, and how violent instrumentation had aggravated his condition.

In May, 1894, Dr. Chismore, of San Francisco, reported to the American Association of Genito-Urinary Surgeons fifty-two cases of prostatics upon whom he had operated for stone with his evacuating lithotrite. Among this number he had had no deaths; he had used no anæsthetic but cocaine, from which no ill effects were noted in any instance. In age his patients ranged from fifty-one to seventy-four years, and the average weight of the stones removed was 149 grains. In some of his cases the operation was completed at one sitting, in others it was continued as long as in each case seemed justifiable; that is to say, until pain was complained of, or until in his judgment there was some evidence of bladder irritability or constitutional disturbance on the part of the patient; any fragments remaining were purposely left in the bladder, to be removed at a subsequent operation.

The use of cocaine for such a purpose was not new; and the leaving in of fragments with repeated sittings seemed like a retrograde step in the history of litholapaxy, but the results reported were so good that I selected three bad cases upon whom to test the method. One of these was a gentleman, aged sixty-four, who has a very difficult bladder and an exceedingly sensitive prostatic urethra. He is a professional man, working with great intensity, and easily gets alkaline fermentation in the bladder and phosphatic urine. He has been a patient of mine for several years, and in my first operation on him by suprapubic cystotomy I removed a stone which weighed 300 grains. Two years later I removed 700 grains by perineal lithotrity; a year after that I performed litholapaxy, under ether, having failed to crush the stone with laughing-gas as the anæsthetic; and again, in January, 1894, litholapaxy, under chloroform. He develops stone very rapidly; I have searched him, pumped him out with the washing-bottle and failed to get any sign of stone, and two weeks later, with the same apparatus, have found a small stone which had evidently formed in the interval. Since hearing Dr. Chismore's experience I have operated on this patient five times; for example, I have operated on him for twenty minutes without entirely removing the stone, and four days later have completed the operation. This year his longest interval of freedom from stone has been from November, 1894, to January, 1895. Immediately after the removal of stone, his intervals of urination lengthen from one hour to six hours. The least change in his health, catching cold, or an excess of intellectual labor seems to produce a condition of urine which causes a very rapid precipitation of phosphates upon the globules of gelatinized pus. In the first operation with cocaine I employed a four per cent. solution, using only one ounce; a few minutes later he became very talkative

and buoyant, and declared that he had never felt better in his life. He went away from my office, and in less than half an hour had an attack of syncope, during which his face was blanched, his extremities cold, and the heart rapid and intermittent. He was restored by the use of whiskey, digitalis, and nitro-glycerine. The operation was performed in my office at one o'clock, and I learned that he had had no food since seven o'clock that morning. Since then I have used two ounces of a two per cent. solution and have had no untoward symptoms.

The second case is that of a man, aged fifty-nine. Upon him also had been performed suprapubic cystotomy, and three years later—that is to say, in June, 1893—perineal lithotrity. I have operated upon him four times, and in his case there have been no unpleasant effects from the cocaine. He has never had any reaction after any of the operations, although I have performed them in my office and have left in fragments of varying size. He also makes calculi very rapidly. These patients live out of town, and their visits are more or less interrupted and infrequent, making it very difficult to keep them in good local condition.

The third case is that of a gentleman, aged sixty-eight, who has intermittent saccharine diabetes, chronic interstitial nephritis, and a difficult bladder to enter, urination being effected by the aid of a silver catheter. He has had two litholapaxies done at intervals of a year by a competent New York surgeon. His symptoms, following the last of these operations, not having been relieved, he came under my care for treatment of his bladder. I found no stone nor fragment, and after some weeks of treatment, his urinary intervals lengthening and the blood disappearing from his urine, he returned to the care of his family doctor, comparatively well. I did not see him again until two and one-half years later, when he sent for me, complaining of pain in his bladder and of frequency of urination, with paroxysms of straining. Searching did not at first determine a calculus in the bladder, but the latter was so sensitive and irritable that I was obliged to put him to bed and have him carefully and gently irrigated. After some weeks of treatment his symptoms were relieved, and searching revealed the suspected stone. Since then I have operated on him five times in the same way as described in the first case. He has had no reaction from the cocaine. On one occasion he had some swelling of the prostatic urethra, causing difficulty in introducing the catheter. This subsided in three days. Other than that he has had no difficulty whatever. At present his intervals of urination are from four to six hours. He shows no tendency to the re-formation of stone, but he has the moderate amount of vesical catarrh which is common in such cases. To him the dread of operation has been so great that he put off having anything done, and went on suffering when he might have had speedy relief. He now knows that there is a comparatively rapid and comfortable manner of removing his stone, should any form, but appreciating his liability to alkaline fermentation and stone, he now comes regularly for treatment.

Of course there is no novelty in cocaine anæsthesia, and I doubt its applicability in cases of large or hard stones in young individuals, where it would be unwise to leave fragments behind to torment an angry bladder. The bladder of prostatics is very tolerant and does not seem to resent the leaving in of fragments, but in my opinion great care should be exercised in treating the bladder, both before and after the operation. This operation does not require the presence of much fluid in the bladder, but it does require considerable dexterity and celerity of movement on the part of the operator in order to avoid prolonged manipulation, with subsequent shock, or risk of damaging the wall of the bladder.

This small stone which I now show you represents an entirely different class of cases from those to which I have thus far called your attention. It was removed from the urethra of a child, four and a half years of age. The only novel thing about the history of the case is, that during one of the child's efforts at straining the stone was forced from the bladder through the prostatic and membranous urethra into the bulbous portion. Here it was retained, not absolutely obstructing the escape of urine, but acting in a measure like a ball valve. The child suffered comparatively little after its escape into the penile urethra, but the urinary symptoms continuing, he was brought under my care. The stone weighs 11 grains and measures $\frac{1}{2} \times \frac{3}{8}$ of an inch. Before operating on the child I endeavored to force the stone out of the urethra by pressure from behind, but it was firmly obstructed at the beginning of the pendulous portion. Accordingly, I pushed it back into the posterior part of the bulbous urethra, and holding it firmly there made an incision through which it was extracted with ease. He made an uneventful recovery, the urine passing through the normal outlet within a few hours after the operation. I have removed calculi of different sizes and constituents from the urethra of the adult, but the passage of a stone (especially of such size), from the bladder of so young a subject into the urethra never having come under my observation before or since, I beg leave to present the case to you, hoping to evoke from you similar experiences.

Another class of cases of exceeding interest, and also within reach of surgical measures, is that of renal calculi. The diagnosis is not always clear, and is usually made by exclusion. In some cases cystoscopy is an aid to it. Pain (renal colic) recurring in one loin or the other, aggravated by jolting or locomotion, associated with kidney elements, and blood in the urine in small quantity, together with an irritation of the testicle of the corresponding side, should lead one to suspect stone and eliminate, if possible, tuberculosis or a neoplasm. At all events, if medication, carried on for a reasonable time, fails to ameliorate the symptoms, the kidney should be explored, lest permanent damage should result to such an important organ. Unless the pain becomes constant, many individuals with suspected renal calculi will refuse operation, preferring to bear their attacks of "kidney colic" rather than to subject themselves to the risks of an operation. From several such cases, five of which were operated on, I have selected three to illustrate clinical features of some interest. One of these is that of a gentleman, aged forty-three, who had suffered from symptoms of renal colic (right kidney) for several years, and finally from hæmaturia and the physical evidences of chronic nephritis. In this case I removed, through a lumbar incision and an incision through the tissues of the kidney, a moderate-sized stone without any particular difficulty. It was irregular in size and friable in character, and during its extraction was broken. The fragments were, as I thought, entirely removed from the pelvis of the kidney with my finger and a small scoop; and the wound through the kidney and its pelvis was thoroughly flushed out with hot boric acid solution. The patient made a very rapid and uneventful recovery. About two weeks after the operation, and two days after he left his bed he had an attack of "colic" in the same kidney on which he had been operated, but which subsided very quickly on lying down. Two weeks later he had another attack of some hours' duration, and passed per urethram a small, flat, irregular, granular body, which I supposed to be one of the fragments of the original stone. After that he remained entirely well for about one year, being absolutely free from pain, when he had a new formation of stone in the same kidney, and after a violent attack of pain, nausea, etc., passed a small, solid gravel by way of the urethra. In my opinion, the attack coming on about a month after the operation is not to be attributed to a re-formation of stone, but to the liberation by locomotion of

a small fragment which in spite of my care had lodged somewhere in the hilum of the kidney.

The second case is that of a lady, of about thirty-five years of age, who had suffered for several years with intermittent attacks of pain in the right lumbar region, with intermittent hæmaturia, and with frequent and painful urination. For nearly a year before I saw her the blood had disappeared, but the pain in the loin had become severe and almost constant, with intense exacerbations, requiring the almost daily use of opiates. When I first saw her she was confined to the house, was greatly emaciated, and her urine, of which she passed from eighty to ninety ounces in twenty-four hours, was of a low specific gravity and contained granular casts. The pain in the right lumbar region radiated downward into the bladder and genitals and was very severe. She suffered extremely, and of course had to be promptly relieved by means of opium. Her condition was such that although an operation seemed hazardous, it demanded some measure of immediate and radical relief; accordingly, I operated upon her by the lumbar incision. When the kidney was reached I felt unwilling to make an incision through an organ already damaged by chronic inflammation, lest its excretory power should be further and dangerously reduced, thus perhaps jeopardizing her life. It seemed to me preferable to let her take the risk of a subsequent urinary fistula. Therefore I fished up the ureter, followed it up to the pelvis of the kidney, turned the latter out into the wound, and opened it wide enough to introduce my finger and search its interior for stone. This was readily found, but its extraction was exceedingly difficult; it would slip away from the finger and hide itself in one of the calices, and it was only after a prolonged effort that I was able to extract it. You see that it is perfectly smooth and hard, slightly flattened on two sides, and that it could very readily escape from an extracting instrument. The opening in the pelvis of the kidney was stitched with catgut, and the wound tamponed with iodoform gauze in such a way as to make gentle compression upon the side of the pelvis in which the incision was made. For five days succeeding the operation the woman was in a very critical condition, suffering from constant nausea and vomiting, with marked vital depression. After that her recovery was uneventful. There was never any leakage of urine, the wound healed by granulation, and from that time to this she has gained steadily in health and weight. From time to time since then she has had attacks of pain in the same kidney, at times quite severe. I have wondered whether another stone was present, or whether another one had formed since the operation; but these attacks having grown less and less frequent, and less and less severe, and her general health having improved in such measure, I have concluded that the pain is due to the efforts of the ureter to expel little masses of pus and epithelium which are still to be found in her urine, the products of the pyelitis, which still persists. Her condition was so critical at the time of the operation that I am satisfied with the course pursued, namely, that it was better to take the risk of a urinary fistula than to damage by surgical traumatism an already diseased kidney.

Another patient under my observation gives a history of renal colic extending over some years, and finally, of pain located in the left side of the abdomen just above the brim of the true pelvis. In this particular locality, along the course of the ureter, can be felt a hard, elongated body, tender upon deep pressure, and which has no relation to any bowel condition. I have advised an exploratory operation with the belief that I shall find an impacted calculus, which I hope to remove by the extra-peritoneal method, and afterward treat the ureter in the same way as I did the pelvis of the kidney in the preceding case. If this should fail and a urinary fistula result, I see no reason why the wound should not be reopened and the edge of the opening in the ureter restitched. Then, to prevent the urine from passing down the ureter, thus interfering with healing, why not open the loin, pass a tube through the tissue of the kidney into its pelvis, and drain away the urine from above? This plan would probably obviate any necessity for a nephrectomy, and leave to the individual sufficient kidney tissue for the requirements of health.

29 East Forty-fourth Street.

ARE THERE SEASONS UNFAVORABLE FOR SURGICAL OPERATIONS?

By ROBERT ABBE, M.D.,

NEW YORK.

SURGEON TO ST. LUKE'S HOSPITAL; PROFESSOR OF CLINICAL SURGERY, POST-GRADUATE SCHOOL, ETC.

The question of this paper, asked equally often of the physician and surgeon by the patient, is worthy of thought. There are many operations, not urgent, which, in the experience of all, have been followed by grave consequences and sometimes death. It may be we have advised them, and they have been done with the utmost care. We are appalled at the result. We ask ourselves, Would it have been wiser to have waited till a better season?

We come to the question of the evening, Is there a good and a bad season for surgical work?

I well remember twenty years since, when on the resident hospital staff, examining a case with Dr. George A. Peters, then visiting surgeon, and being impressed by his advice to the patient not to be in too much hurry to have an operation, but to return at a better season. Now Dr. Peters was always a cautious surgeon. He would usually in a doubtful case "let it simmer," as he was wont to say, and never rushed into uncertain operations. We all know, however, that he was a good observer. A disease would have to declare itself symptom by symptom, spell itself out letter by letter, as it were, before he would pronounce its name. Such was the impression his service left upon the minds of his house staff. Hence, he seemed never to rush into doubtful diagnosis or risky operations. We all know, however, that he was a successful surgeon, and that added to his powers of observation he had a well-balanced mind and worked conscientiously for the welfare of his client. His observations, then, that there were good and bad seasons for surgical work, left an impression that has frequently obtruded itself on my thoughts during twenty years of work.

It is, and should be, one of the many complicated considerations prevailing in the mind of a physician or surgeon in giving advice, which constitute what is technically and popularly recognized as the doctor's judgment—for as one grows in years he finds that not the mere skill of a mechanical surgeon nor the accumulation of scientific facts form the basis of sound judgment. It is to aid us in having a clearer perception of this question that I invite discussion.

Why has the public mind had the idea that there is a difference in relative danger at varying seasons? Probably because we all know the effect of "dog days" on healthy natures; and of extreme heat, when many say, "If this keeps on another day we shall die;" and it is undoubtedly true that prolonged heated days and nights swell the mortality lists, and the weaker ones drop off. We have all been conscious of extended periods of depressing weather, heavy gloomy days when we work with difficulty.

The public knows that at certain hours of night the vital powers are at an ebb; that there are seasons when sudden deaths seem to prevail; that epidemics of grippe, etc., come at times and close our schools—when the general health seems to be below par. Naturally, then, the legitimate inference is that if they are to be operated on, they will choose the best season, if possible, to wait.

In the surgical views of the last generation we will find corroboration of Dr. Peters's remark, which would not prevail to-day.

Addinel Hewson, in an article on the influence of the weather on the results of surgical operations, written thirty years ago, states that all operators on the eye were accustomed to observe many instances of failure in operations on cataract, iridectomy, etc., due to unfavorable changes in the weather, and asserts that he had allowed the atmospheric considerations to influence him in advising operations or postponement, regarding eye-work as typical of all surgical interference. He then takes about three hundred cases of amputations for injuries, during several years in one hospital, laboriously analyzes the weather about the time of each operation, and finds that according to season a much larger proportion of deaths resulted from pyæmia in summer and from shock in winter. We may dismiss pyæmia from our minds, as it has almost been vanished with erysipelas from our wards, and look only on the fact as a curiosity that in pre-Listerian days it was more common in summer owing to bacterial activity and putrescence in hot weather. But what interests us more is the deduction regarding shock, that it is more common in winter than in summer. This does not appeal to reason, and when we see that from his statistics he had no mortality from it in September, August, and January, it is evidently an accident of statistical summary with which winter is thus credited.

Of more interest is a barometric note he makes: Out of 259 amputations 54 were fatal, 11 having been operated on during an ascending barometer, 35 when it was descending, 8 when it was stationary. He asserts that the barometer is a guide for operations when a choice of time is at his disposal.

B. W. Richardson also recognizes the time as favorable for operations when the barometer is rising, or high. Regarding season, he has written from the stand-point of twenty-five years ago, that from a study of one hundred and thirty-nine thousand deaths he finds the prevailing deaths from surgical fever to be in winter, when, he observes, all febrile diseases, scarlet fever, erysipelas, etc., prevail. This he backs up by quoting positive facts of one operator's work and one class of operations, namely ovariotomies, and he finds that, because Spencer Wells during one year had a mortality of about 1 in 5 in the first quarter, 1 in 13 in the second, 1 in 5 in the third, and 1 in 2 in the fourth, he must conclude that spring offers the best, and winter the worst months for success.

From the present stand-point of surgical pathology we see how utterly at fault so keen an observer as Richardson was. I have quoted him only to emphasize the fact that the idea he announces has had widespread recognition.

Richardson and Moffat discovered that south winds brought ozone and their prevalence corresponded with seasons of fever, hence unfavorable for surgical work. The elder Gross, on the other hand, said he could not remember ever to have postponed an operation on account of the season.

Seasons undoubtedly act with varying power on different persons. There are those who suffer greatly from heat, prostration, syncope, etc., and those who are peculiarly sensitive to changes to cold. The highest state of the functions of the body—respiratory, muscular, etc.—is in the spring, through summer, and toward autumn. After that the carbonic acid vapor exhaled, the volume of air inspired, etc., all lessen, autumn representing the minimum of normal functional activity, as shown by most careful physiological experiments. In other words the system is alive to changes, as the flora and forests are to take on new life. And it is reasonable to say that an augmented reparative power may be looked for. This we see in every chronic case in hospitals during spring and early summer; I think, though, improvement may be due somewhat to the admission of air to the rooms, and the increase in sunshine. Nevertheless the spring offers a helpful power to the surgeon, not only in the recuperative physical action of the body, but in the increased mental attitude of convalescents, who not only sit by open windows, but share the joyousness of the birds, flowers, and sunlight.

Traumatic fever does not seem to be more intense in hot weather, and the septic febrile exacerbations so constantly regarded as malarial at one time, and for which quinine is so often given when the knife should be used to evacuate hidden pus, has been spoken of often as to be looked for in autumn season. In my experience, though in my ignorance I have often said of this, "It may be malaria, let us try quinine," I am free to say I do not recall a single instance where I have been rewarded by the relief of my patient. Hence I have grown to discount this possible complication of surgical work by autumn malarial influence. Yet, if one knew his patient had been in a malarial region during the summer, it would be wrong not to heed the possibility of an outbreak, and advise a course of quinine before operation.

There is often a tendency of work to run in groups. We will see, for example, four or six cases of furunculosis during a month of the year, and go months afterward without another case.

The same experience applies to diffuse phlegmonous inflammations, carbuncles, suppurative ear troubles, purulent tonsillitis, etc. There are months when these prevail. Not the hot months, though we would expect bacterial growth of all sorts to be favored by heat. They seem to be rather the winter and spring months, when from bad housing or epidemic aërial influence the season seems to breed disease. These cause much surgical work, but "do they complicate the cases of impending operation?" is entirely another question. If during January and February the cases of appendicitis of a virulent type prevail, and pneumonia, grippe, diphtheria, and erysipelas are more numerous, does it call for a check of surgical work in cases that can be postponed, as, for example, laparotomies, operation for lipomata, hemorrhoids, calculous, urethral work, ovarian tumors, etc.? That can be answered by considering the death-list in surgical cases at different seasons, and as far as I can discover from my own work, the best results run uniformly through these months.

Do we see pneumonia complicating surgical work during the prevailing epidemics of pneumonia? My experience is quite in the negative. This complication as a sequel of operation is now recognized as due to preventable causes in most cases, and is seen more in certain classes of work, as after tongue excision, strangulated hernias, where feculent vomiting has been associated, tracheotomies, and like cases where inhalation of impure or septic particles have begotten septic pneumonia. Besides these there are some which are thought to be incident to etherization or prolonged dorsal decubitus, but which I feel sure are usually due to brief, though sufficient, chilling of the patient during or just after the operation, or to unrecognized cardiac weakness with secondary pulmonary œdema. Of this latter I have seen one striking illustration this winter in a hospital case where I had performed Kocher's tongue extirpation with perfect convalescence up to the sixth day. The patient had so weak a heart action before operation, that the pulse could hardly be felt at the wrist, though she was in good color and had a fair apex-beat. On the sixth day she had increasing cyanosis, pulmonary râles, and some increase in respiration, frothy expectoration, and oppression. The house surgeon treated her as a case of pneumonia, and failed to notify me. At the end of thirty-six hours she died, and on investigation I found he had signed the certificate pneumonia, whereas she had œdema from cardiac failure. Had he given nitro-glycerine and turned his attention only to the heart, he would probably have

saved her. I had the small satisfaction, at least, of saving the much-abused "pneumonia" from the credit of causing a post-operative death.

Again, in infant hospitals whose subjects afford so constant an illustration of pneumonia complicating many maladies, we have an example of the effect of cold. During the past few weeks, when the sudden cold wave came, I know wards full of infants where the nurses were for a day and a night unable to get the temperature above 50° F. Seven cases of pneumonia resulted, of which three died.

In general surgical wards of our large hospitals, my experience is, that pneumonia is extremely rare, since I have provided for ample warmth and protection for the unconscious patient during and after operation, and for the preventable septic infection from vomit and inhalation by washing out the stomach of hernia cases vomiting, and the liberal use of iodoform packing and boracic acid in mouth, throat, and nasal surgery.

I may record here that I have twice had my private patients suffer after having their nasal bones sawed out under cocaine by specialists and being allowed to continue to go to business. One came down promptly with diphtheria and was saved with difficulty. The other had septic pneumonia and died. Hence I have grown to feel that pneumonia, or so-called pneumonia, after surgical work, which has been sometimes considered a seasonable complication, is really preventable, and that even when there is a prevailing epidemic a given number of surgical patients are even less likely to suffer from it than a corresponding number of the community at large, because they are protected by being in equable surroundings. An epidemic beginning in December, which has recurred for the sixth season and cost three thousand lives in New York State alone last year, according to the record of the State Board of Health, and in previous years five thousand to eight thousand, might be considered a menace to surgical work, did not our hospital wards disprove its effect.

I have thought it would be an argument if the surgical work among infants showed sensitiveness to season, but on analyzing my work of the last two years I find that of more than 100 operations on very young infants with 7 deaths, 1 occurred in April, 2 in June, 2 in October, 1 in November, 1 in December. The largest number of operations being in June and July, with smallest proportion of deaths. Nevertheless I have thought that the summer months were apt to be disastrous for children operated on, on account of the onset of diarrhœa troubles, which I have observed sometimes set in, after hare-lip operations, for instance, when sprue was present. Atmospheric influences in hot weather on operations about the respiratory passages I have taught were apt to complicate, but on looking over 13 hare-lip operations in two years, many of them bad double cases, I find 1 death in June, in 4 cases, none in 3 cases in July, 1 out of 2 in October, and 1 out of 3 in December, other months no deaths.

The argument then for children as for adults is in favor of ignoring the season. Indeed the experience of surgeons to-day will show that, as an illustration of a traumatism, the conduct and results of fractured bones are entirely independent of the season, and, for all practical purposes, any properly conducted surgical operation with aseptic work, and covered in by aseptic dressings is equivalent to a subcutaneous wound which proceeds as harmlessly as a simple fracture.

We may feel then, I believe, that one is in a position to-day to say to any patient contemplating operation, "It is as well to do it now as any other time." For my part, it is a satisfaction to have dispelled the delusion that this might not be true, concerning which I have heretofore had a slight doubt.

It was Goethe who said, "Blest be the man who cures my doubts, and gives me none of his"—and it will, I hope, be of service to the members present to have a definite and final thought on the subject.

THE EARLY DIAGNOSIS OF CANCER OF THE STOMACH.[1]

By MORRIS MANGES, A.M., M.D.,

NEW YORK.

ASSISTANT VISITING PHYSICIAN TO MOUNT SINAI HOSPITAL, AND LECTURER ON GENERAL MEDICINE AT THE NEW YORK POLYCLINIC.

Carcinoma of the stomach is a surgical disease. Although, *a priori*, this axiom seems self-evident, yet its force is made more manifest by the fruitless search for panaceas for this disease. Every remedy thus far proposed for the medical treatment of gastric carcinoma has proven to be worthless, and even the much-vaunted condurango has been relegated to the list of stomachics. A similar fate may be predicted of chlorate of soda, the drug most recently recommended as a cure for gastric cancer.[2] In my hands it has been absolutely worthless; I believe but one paper has been written in its favor since it was first introduced. On the other hand, the surgeons have reported a successively larger number of radical cures; and with the improvement of the technique we have every reason to believe that the various operative procedures will be even more successful. Thus the mortality after resection of the pylorus up to 1885, was seventy-three per cent.; 250 cases reported up to 1890 had a mortality of fifty-eight per cent.; Billroth's mortality up to 1890 was only fifty-five per cent. In 1893, Kocher lost but 2 cases out of 9, *i.e.*, twenty-two per cent., while Hahn lost 1 out 4 which he operated in 1894. The statistics of gastro-enterostomy are even better, as may be judged from the statement of Hahn that he was successful in all of the 9 cases which he operated in 1894.

If we bear in mind that the first pylorectomy was performed in 1878, and that in nearly all of the cases the operation was only performed where there was a palpable tumor, such a reduction in the mortality of so grave an operation is but little short of marvellous, and it is therefore somewhat surprising to find Ewald taking the reactionary stand he did at the recent discussion of this subject at the Berlin Verein für Innere Medicin. From what we now know, we can safely say that every reputed cure of cancer of the stomach by drugs has been a mistake in diagnosis. Furthermore, even if we cannot remove the neoplasm, we can certainly retard its growth and make the patient's life much more comfortable by gastro-enterostomy.

It were well, then, if the time which is now being spent in searching for specific drugs were devoted to an improvement in our methods of diagnosis, especially such as will enable us to recognize cancers at a much earlier period than has heretofore been possible. A timely operation presupposes a timely diagnosis, and the prognosis of an early operation is improved not alone by the smaller size of the tumor and fewer adhesions, but what is equally important, the patient's strength has not been sapped by the disease.

Our present means of diagnosis are certainly inadequate for this purpose. To wait for a tumor, as is usually recommended, is to wait too long; for it is seldom present before the third or sixth month of the disease, and usually only becomes distinctly palpable in the latter half of the disease, or toward the end of the patient's life. Bouveret claims that the presence of a palpable tumor indicates that the disease has passed beyond the limits of the stomach. Czerny states the presence of a distinctly palpable tumor is a contra-indication to a radical operation.

I need not now detain you with our present criteria, as you are all more or less familiar with them, but shall merely direct your attention to a few salient points on the early symptoms.

Heredity and habits are very unimportant factors in the history of this disease. Two symptoms deserve

[1] Read before the Metropolitan Medical Society, March 26, 1895.
[2] Brissaud: Gaz. Méd. de Strasbourg, May 1, 1894.

attention : one is Leube's statement that the onset of the disease is usually sudden and without any apparent causes in a person who has previously been free from stomach trouble. Schüle[1] studied one hundred and ninety-eight cases carefully, and found the symptoms in seventy-seven per cent. of his cases. Another fairly constant symptom is a more or less marked anorexia, although in a few cases the appetite may at first be increased. The early repugnance toward meat is a symptom to which attention has frequently been called. Vomiting is of early occurrence in cases in which the pyloric orifice is soon affected. Hæmatemesis is rarely a timely symptom. Anæmia and loss of weight are rarely missed, even soon after the onset of the disease. Changes in the motor powers of the stomach are very soon found in these cases, and are among the most important symptoms, as will be shown later on. Schüle denies this, and states that he found a decrease in only thirteen per cent. of his cases. In this he is at variance with most writers, who are quite unanimous that the motility of the stomach is decidedly lessened. Finally I must mention the absence of free hydrochloric acid, pepsin, and rennet-ferment—the results of the atrophy of the gastric mucosa. The significance of the latter has been so often discussed that no time need now be spent in its consideration.

Recognizing the uncertainty of all symptoms, especially in the early diagnosis of the disease, Boas was led to study the relations of lactic acid in gastric cancer. In a previous paper[2] I directed attention to the value of these researches, which I propose to discuss here at greater length.

A faulty technique had led to the belief that lactic acid is a normal constituent of the stomach-contents during the early stages of digestion ; Rosenheim even claimed that it was at any time to be demonstrated in the chyme if we use sufficiently delicate methods. However Boas's researches have finally settled the long-mooted question of lactic or hydrochloric acid by absolutely proving that in all the tests breakfasts and dinners contain lactic acid or its salts. Hence we must not use the various breads, rolls, cakes, milk, and meat. Instead he has proposed a simple meal which consists of an oatmeal gruel (one tablespoonful of oatmeal to one quart of water) to which nothing has been added except a little salt. Another important point is that all remnants of former meals must be removed by a preliminary lavage of the stomach. The best time to do this is in the evening, and then we may give the oatmeal gruel. It is expressed on the following morning.

Boas also studied the various tests for lactic acid, and showed that if absolute certainty is desired, they must be discarded and new methods of his own substituted.

As is well known, Uffelmann's reagent is prepared by adding two to three drops of pure carbolic acid to 20 c.c. of water containing a few drops of tincture of ferric chloride ; the amethyst blue solution which results from the thorough shaking up of this mixture is so unstable that it must always be freshly prepared. The reagent is a delicate one, and even 0.1 per cent. of lactic acid will give a distinct canary-yellow color. Many substances which may occur in stomach contents also discolor the solution ; these are butyric, acetic, and formic acids, phosphates, alcohol, grape sugar, and mineral acids when present in large amounts. However, the reaction produced by these substances (as butyric and acetic acids) is somewhat different from that due to lactic acid and can readily be differentiated by the practised eye, or is not produced after the stomach contents have been extracted with ether. This can readily be done by shaking 2 to 3 c.c. of chyme with 50 to 100 c.c. of ether (which must be free from alcohol) in a separatory funnel ; decant the ether layer into a beaker,[1] evaporate to dryness over a water-bath or a vessel of hot water ; dissolve the residue in 5 c.c. of water, evaporate to a small residue over a flame and add by means of a dropper one to two drops of Uffelmann's reagent. Boas quotes with his approval the modification of Fleischer,[2] in which the ether is not evaporated, but the carbolate of iron solution is added directly to the ether ; shake up vigorously, and if lactic acid is present the lower layer will assume the characteristic yellow color.

The tests proposed by Boas for the absolutely exact determination of lactic acid are by no means as simple and consume too much time to be of clinical value to the busy practitioner. "When lactic acid is heated slowly and cautiously with oxidizing agents it splits up into formic acid and acetic aldehyde. The presence of the latter body can be ascertained by many tests and its quantity determined. The iodoform test is suited for both quantitative and qualitative work. The oxidation is obtained with manganese binoxide and sulphuric acid ; if the aldehyde is then conducted into an alkaline solution of iodine, iodoform is formed. Under proper precautions, a given quantity of aldehyde decomposes a given quantity of the iodine solution, and hence the amount of the former is obtained. Ketone and alcohol, which also give this iodoform reaction, are gotten rid of by boiling the fluid to be examined down to a thick sirupy consistency. Carbohydrates heated with oxidizing agents also give off aldehyde, so that the lactic acid must first be extracted with ether."[3]

Extended researches with this test showed that lactic acid is not a normal ingredient of the stomach contents, and that it is also absent in chronic gastritis, atony of the stomach, neuroses, and non-malignant pyloric stenosis. On the other hand, in 20 out of 21 cases of cancer it was constantly present, and that, too, in quantities large enough to give very positive reactions with Uffelmann's reagent. HCl was absent in all these cases ; no tumor was present in three cases ; in 16 the lesser curvature was involved, in 3 the pylorus, in 1 the anterior wall ; in the remaining case the site was uncertain. In all the cases there was stagnation of the stomach contents.

As the result of these observations Boas claims that with the necessary precautions as to the test meals, etc., the presence of large quantities of lactic acid, combined with stagnation of the stomach contents and the absence of hydrochloric acid, is diagnostic of cancer of the stomach, even in the absence of a palpable tumor.

Bouveret[4] states that he believed lactic acid may be present in marked chronic gastritis and neuroses where there is stagnation of the chyme and the quantity of HCl lessened. As opposed to these theoretical considerations I may state that Cohnheim[5] failed to find lactic acid in six cases of gactrectasis, and fourteen cases of advanced chronic gastritis in which HCl was absent. He also found lactic acid in nine out of ten gastric cancers, and also in four cases of œsophageal carcinoma. He also gives details of a case in which an early diagnosis of cancer, long before a tumor could be palpated, in which the diagnosis was proven by autopsy. Ewald states that he found large quantities of lactic acid in 22 out of 24 cases of gastric cancer, *i.e.*, ninety-two per cent., while Strauss found lactic acid in but 5 out of 129 cases of non-malignant gastric disorders, *i.e.*, four per cent.; it was absent in gastric ulcer, gastroptosis, neuroses, and dilatation.

I believe that Boas's test will lose much of its value as a clinical method, if the complicated aldehyde test which he has proposed must be carried out in all cases.

[2] MEDICAL RECORD, February 2, 1895.

[1] A test-tube ought not to be used for this purpose, as the vapor of ether will come off in "jumps," so that much of the contents of the tube may be lost. It may also be advisable to call attention to the fact that all these procedures should be carried on away from any open flame.

[5] Deutsche med. Wochenschrift, May 17, 1894.

My own belief is that if we take the precautions of carefully cleansing the stomach and then giving oatmeal gruel as the test meal, Uffelmann's reaction, if well marked, will suffice. Pariser[1] comes to the same conclusion. Even Boas[2] admits that the results of Uffelmann's reagent are conclusive in those cases in which we obtain an intense lemon-yellow color after adding only a few drops of the filtrate of the gruel, or still better, its ethereal extract (to which one or two drops of phosphoric acid have previously been added.) Greater certainty may be obtained by comparing the reaction to the color obtained with a control test with the same number of drops of a 0.2 to 0.3 per cent. solution of lactic acid. But if the result is doubtful, the aldehyde test is to be employed.

So far as can at present be definitely stated, it would seem that the presence of the large quantities of lactic acid is due to the stagnation of the stomach contents and the absence of hydrochloric acid, which offer very favorable conditions for the rapid growth of the lactic acid bacilli. There must be other unknown factors which the active work which is now being done on the gastric fermentations may reveal; although it must be borne in mind that nowhere is lactic acid produced in such quantities as in the cases in question. Stewart[3] has suggested the possibility of the production of a lactic-acid enzyme through the specific agency of the carcinoma.

It is to be specially noted that the stagnation of the stomach contents is not necessarily due to stenosis of the pylorus, but to an infiltration of the muscular layer of the stomach by the neoplasm. Inasmuch as this infiltration is quite marked at an early stage, even before a palpable tumor can be felt, we may have a ready explanation of the early occurrence of the stagnation without evidences of dilatation.

Boas also directs attention to the fact that the absence of lactic acid does not necessarily exclude the presence of a gastric cancer, as it may readily be understood that the conditions favorable to the production of lactic acid do not occur in every case. And yet, if we bear in mind in what a very small proportion of cases lactic acid has been found in non-malignant diseases of the stomach, it may safely be predicated that the absence of this acid is a strong point against the existence of cancer. I am sure that this test will be of value in a large class of doubtful cases of chronic gastritis in which the constitutional symptoms are very well marked and the emaciation quite pronounced, the latter being the result of the patient taking less food in order to escape pain, etc. HCl is very much lessened or absent, and the general appearance of the patient leads us to suspect malignant disease.

The following case, which was admitted to Dr. Alfred Meyer's service at the Mount Sinai Hospital in December, 1894, demonstrated the value of Boas's test in excluding gastric cancer. The patient was a woman, forty-four years of age, who had had some abdominal trouble ten years previously. For four months she complained of vomiting coming on a few hours after eating, preceded by dull, aching pain in the stomach and back. Vomiting relieved the pain. Constipation; amount of urine lessened: globus hystericus. Examination of the abdomen showed that the greater curvature was two inches below the umbilicus, although palpation even under anæsthesia failed to reveal any tumor. Repeated examination of the stomach contents showed that the total acidity varied between 0.65 and 0.87 per cent.; no lactic acid. Urine normal. Hæmaglobin, 65 per cent.; red blood cells, 3,725,000; white cells, 30,000.

All treatment having proved useless, she was operated on by Dr. Gerster. On making a median incision just below the ensiform cartilage, it was found that so closely were the stomach, liver, and intestines bound down by adhesions, that practically no peritoneal cavity existed. Careful examination failed to reveal any tumor. A few large stones were felt in the gall-bladder. The latter was stitched into the wound. The woman died six weeks later, and at the autopsy no cancer was found in the stomach. Similar cases are reported by Stewart[1] and Friedenwald.[2]

Finally, Boas states that we must not depend on this one sign alone, but that it must be associated with the absence of HCl and stagnation of the stomach-contents, and the subjective symptoms above described.

The practical value of Boas's researches has been shown by Cohnheim, Oppler, Rosenheim, Hammerschlag, Schüle, Strauss, Pariser, Stewart, Friedenwald, and others. Hammerschlag[3] was enabled to diagnosticate two cases of gastric cancer early enough to permit radical operation before a tumor was palpable. Rosenheim[4] states that although his own experience and that of Ewald have shown that marked lactic-acid reactions were occasionally obtainable in conditions other than cancer, "yet these were always exceptions, and in the great majority of cases, cancer was found where there was lactic-acid fermentation." Friedenwald's recent paper[5] deserves notice as being the most elaborate and careful study of this subject which has thus far been published. In twenty-nine examinations in nine patients, three of whom were healthy individuals, the other six being cases of nervous dyspepsia, no lactic acid could be found. The same result was obtained in four cases of superacidity, eight cases of atony, two of simple dilatation, eight of chronic gastritis, and four of secondary gastric catarrh. Large quantities of lactic acid were found in four cases of cancer. In all of these examinations, the exact details of Boas's aldehyde test were carried out. Friedenwald's conclusions are that "lactic-acid is never produced after the ingestion of carbohydrate food in any chronic non-malignant disease of the stomach."

I desire to add a few details of two cases in which early diagnosis of gastric cancer were made by this method.

Mrs. F——, sixty years of age. Family history negative. Her only previous trouble was a very obstinate constipation. On December 15, 1893, she complained of having emaciated considerably, and sought relief for pains which came on soon after eating; they were quite severe, began in the epigastrium and radiated backward; anorexia. Examination showed some resistance in the epigastrium; size of stomach was normal; liver somewhat enlarged; right floating kidney. Restricted diet, Carlsbad salt, and bismuth ordered.

December 30th.—Expressed 20 c.c. one hour and a quarter after taking Ewald's test breakfast. It was but slightly digested; acid to litmus; slight reaction to congo red and tropælin papers; Günzburg's test negative; well-marked Uffelmann reaction. Total acidity, 20. Disc of albumin digested only after adding HCl and pepsin.

January 10th.—Preliminary lavage; oatmeal gruel; expression brought up 30 c.c. Reactions same as above; total acidity, 16. Marked lactic-acid reaction both with the stomach contents and ethereal extract.

January 24th.—Had lost seven pounds in two weeks, yet she had fewer complaints since taking large doses of HCl and pineapple-juice at meals.

For a month felt fairly well, and as the result of taking larger quantities of food she gained several pounds in weight. An indiscretion in diet brought back the old complaints, after which she again began to lose ground.

March 1st.—In the left lower portion of the epigastrium a small, hard mass could be palpated, and the whole epigastrium is more tender and resistant than

[5] Loc. cit.

before; succussion. From now on the patient lost ground much more rapidly; complete anorexia and severe pain. The tumor gradually became larger and more nodular; its growth was mainly toward the right side. Hydrochloric acid was constantly absent, while lactic acid could always be demonstrated in large quantities in the stomach contents.

May 18th.—Vomits twice daily; pains are very severe; obstinate constipation. The tumor has grown much larger, so that it could be felt as a large hard mass extending across the abdomen at the level of the umbilicus. Peristaltic waves now visible, and size of stomach increased. A few weeks later had coffee-ground vomit and tarry stools. Signs of gastrectasis very well marked; vomited large quantities of very offensive fluid; tumor had extended especially on the right side, so that now it was of very large size—indeed, when the patient died, a month later, the whole stomach seemed to be converted into a tumor.

There was no autopsy; a very interesting feature of the case was the occurrence of the symptoms of dilatation as the neoplasm gradually grew over toward the pylorus.

Mr. A——, forty-four years of age, came under my care January, 1894. Previous history included neurasthenia and malaria. His present trouble began five months previously with belching and distress soon after taking food; there was only occasionally pain in the epigastrium; vomiting occurred now and then; "once it was as black as ink." Bowels regular; appetite fair. His chief complaint was the constant loss of weight, which began soon after the appearance of the above symptoms. The man was pale and sallow, but by no means emaciated, although he had evidently lost much flesh. Tongue somewhat coated. Heart and lungs normal; liver not enlarged or tender; spleen just palpable; stomach not dilated, the lower border being one inch above the umbilicus; no succussion. Palpation of the epigastrium showed resistance, but nothing definite could be mapped out. One hour after test-breakfast expressed 50 c.c. of acid stomach contents; total acidity 50; no free hydrochloric acid; very marked reaction with Uffelmann's reagent, even after adding only one or two drops; same reaction with the ethereal extract. No pepsin; but rennet-fervent present. Microscopic examination negative.

A few days later oatmeal gruel was given after preliminary lavage; the fluid expressed again showed an absence of HCl, and gave a very decided Uffelmann reaction.

The patient did not return till four months later, when a small tumor could easily be palpated at the pylorus; it was movable externally, and lying above it a small body like a gland could be felt. The subsequent history of the patient could not be ascertained.

Boas's test has recently been criticised by Bial.[1] He carefully studied a case of ulcer of the stomach with atrophic gastritis and gastrectasis. A very much emaciated man was admitted to Ewald's clinic for anorexia, feeling of weight in the epigastrium, and vomiting. On examination the stomach was found dilated, and lactic acid was demonstrated with Boas's method, after the oatmeal gruel had been given. A few days later the man became drowsy; vomiting persisted in spite of lavage, and death occurred in coma. The vomit was free from HCl, but contained lactic acid. Although no tumor was palpable, in view of the above results a gastric cancer was diagnosticated. At the autopsy several ulcers and cicatrices were found near the pylorus. At the cardia there was an atrophic chronic gastritis.

He also quotes the cases of Thayer and Rosenheim as militating against the method. Such criticism is not just, as in these two cases the very important details of preliminary lavage and the use of the gruel were not carried out. For the same reason the results of Johnson and Behm[1] become useless; they report that in 153 persons lactic acid was found and HCl was absent, and yet only 19 of these patients had gastric cancer. How Bial's case is to be explained remains to be seen. Even it does not lessen the practical value of the test, for Boas himself does not claim that lactic acid is to be found in every case of gastric cancer, but that its occurrence is about equal to that of the absence of HCl. It is the association of the absence of HCl and the presence of lactic acid which is of importance. Hence the method is useless in those cases in which HCl persists. Nor must we forget Rosenheim's statement that in twelve to fifteen per cent. of all cases of cancer of the stomach no diagnosis is possible.

Recently attention has been called to other factors which may be of importance in establishing the diagnosis of gastric carcinoma. Oppler[2] has described long, thread-like bacilli, which are immobile and often occur in enormous numbers in stagnating stomach-contents when hydrochloric acid is absent and large quantities of lactic acid are present. Cultures have thus far been unsuccessful. Boas[3] corroborates this assertion.

The same authors have also found that sarcinæ are very rarely seen in the above-described kind of stomach contents. Oppler states that even after adding pure cultures of sarcinae to such stomach-contents, after twenty-four hours neither were any of the organisms to be found with the microscope nor could any cultures be obtained. Furthermore, sulphuretted hydrogen, which may be found in the stagnating chyme of a non-malignant dilatation, is not found in cancer. "It would thus appear that the substances produced in the stomach-contents in cancer are different than those produced by stagnation under other conditions." Hammerschlag[4] claims that the absence of pepsin is also a very important symptom in the early diagnosis of carcinoma. This statement is denied by Oppler. Should further observation establish the correctness of these statements our methods of differential diagnosis will have been much improved.

Finally, another method by means of which some gastric tumors may be diagnosticated much earlier than has been done heretofore is gastro-diaphany. Only such growths as are situated on the anterior wall of the stomach can be discovered in this way. Einhorn, Kuttner, and Jacobsohn[5] have reported cases in which they recognized tumors with the gastrodiaphone.

In conclusion I would state that if future researches shall establish the claims of the various methods above described, not alone will cancer of the stomach be diagnosticated more readily, but, what is of far greater importance, we will be enabled to cope with this disease much more effectively than we have done heretofore.

941 Madison Avenue.

Stones in Birds' Stomachs.—Gustave Radde has examined the stomachs of many migratory birds in the Crimea, and found that they were almost invariably filled with small pebbles, which he thinks are swallowed in order to mitigate the pangs of hunger in their flight.

The Confusion of Tongues.—The date of the Ninth International Congress of Hygiene and Demography, which is to be held at Madrid in 1897, has now been fixed from October 11th to 18th. The *British Medical Journal* says that the Spanish Government has sanctioned the use of no fewer than six official languages, namely, Spanish, Portuguese, French, Italian, English, and German. At this rate international congresses bid fair to be excellent object-lessons in the "confusion of tongues."

SOME FACTS CONCERNING DIPSOMANIA.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

A PHYSICIAN recently sent me a marked copy of the MEDICAL RECORD referring to an editorial "On the Power of a Dipsomaniac," expressing an opinion that I would doubtless endorse it freely, in a half-implied sarcasm.

This gives me an opportunity to say that this editorial gives an outline of some very important facts not understood at present; facts that will revolutionize many of the theories of the present time. It will be of interest to group some of these facts and ask the reader to verify them in his practice and experience. Nearly all inebriates seem to divide into three classes. The members of one class are steady drinkers, sometimes in so-called moderation, and rarely intoxicated; others drink excessively, and are constantly under the influence of spirits. They are most aptly termed demented, and sooner or later merge into dementia. Those of the second class are the periodic cases who drink after distinct free intervals. The drink paroxysm ends after the lapse of a certain time, and begins at another time equally distant. These are the epileptoid cases, and frequently develop epilepsy. The special symptom is the gathering and explosive character of nerve energies. The drink paroxysm, like a storm, dominates every impulse for a time, then dies out, only to recur again in like circumstances and conditions. The brain capacity in the free intervals seems but little disturbed; not unfrequently it is more active, and only in the later stages are there marked changes.

The members of the third class are called dipsomaniacs, and are distinctly insane, belonging to the class of impulsive and reasoning maniacs. The drink mania is a symptom of the dominance of a morbid idea, which may change in many ways. These cases include that large unknown class of so-called "Border Liners" who live on the "frontiers of insanity," crossing back and forth all the time. Neurotics, paranoiacs, moral paralytics, religio-maniacs, eccentrics, and enthusiasts of every grade are all seen in this class. Some of these persons manifest ability and occupy places of trust. When not suffering from the drink paroxysm they are frequently very useful and respected citizens. Some energetic reformers belong to this class, and may make a great stir in the world.

The reader will recall a number of cases of this character, who are known to have drink periods, and who in the intervals display much mental force. It will be observed that such cases are wanting in originality and prudence. They may act along accustomed lines with judgment, but beyond this they are unreasoning and unsound mentally.

The case mentioned in the MEDICAL RECORD has many parallels in all parts of the country. One instance will be recognized in New England, where a man of this class wrecked a bank and a large manufactory in the most childish swindling scheme. He was sent to State prison, and became insane a few months later.

Recently a man with great enthusiasm and energy, known to have drink periods, was placed at the head of a railroad. He made the most extravagant business arrangements, and displayed such bad judgment that the road went into the hands of a receiver finally.

The following case, under my care some time ago, illustrates many of this class: H—— came from a family in which inebriety, genius, and various eccentricities had appeared in every member. He took many honors as a student, and as a lawyer was a very brilliant, promising man. At twenty-five he began to have drink paroxysms in seclusion, at long, uncertain intervals. From this time he displayed great changes of character and conduct. In the midst of some important trial he would become ill, which meant that he would drink to stupor at night, and be sick all the next day. He was elected to Congress, and at times showed much power and excellent judgment; then displayed the very opposite traits. He became involved in low political rings, then posed as an aggressive opponent of corruption. He defended the whiskey ring, then opposed it with wild zeal. In his home life the same strange medley of inconsistent conduct and theories prevailed. His drink paroxysms came on at most unexpected periods, and were usually concealed. After a short period of treatment he abstained for nearly two years, but the same irregular conduct continued. He relapsed, and is still drinking as before. It may be said that every enterprise or theory he becomes identified with is pressed with energy and skill up to a certain unknown point, then abandoned or neglected or denounced with equal energy. He is both a builder and wrecker, and that without any ostensible purpose or motive. His dipsomania is not recognized, and he is only known to have "drink spells" at times. In reality he is a dangerous man, whose conduct has very seriously injured the community in many ways.

The gold-cure schemes have brought out this class, who, after a short experience in so-called treatment, became hysterical defenders of its merits. They have been most active in organizing branch cures, and enlisting capital, by the most extravagant promises of blessings and pecuniary rewards. Becoming officers of these companies sooner or later they relapse, and the pecuniary promises fail, and only the so-called blessings remain. It is only a repetition of common experience, when those who boast most loudly of restoration are the first to fall. The dipsomaniac who attempts the difficult task of curing others in like condition always fails, from conditions that are beyond his power of control.

The exciting cause of the drink paroxysm is often very clear, and can be predicted in advance. In some cases unexpected success in business or special recognition that appeals to his vanity is always followed by a drink craze. Sudden failures or criticisms or anticipated strains provoke the same thirst. Some of these cases show great resistance to the ordinary temptations of contagion of surroundings, strains of business and social life, and when these and other temptations are removed, fall abjectly.

An almost infinite variety of conditions act and react in producing or checking drink paroxysms. At one time a man who is known to have drink paroxysms under certain circumstances, will manifest an unexpected power of resistance, and pass through periods of much mental strain, then relapse at a most unusual time and place. A nephew of a former President, a dipsomaniac, was very poor, with a large family dependent on him. He had abstained for over a year, when called to hear the reading of his uncle's will. This will provided that in the advent of his remaining sober one year from the time of the reading of this will, the trustees should pay him one hundred thousand dollars. Within an hour after the reading of the will he drank to stupor, and continued for a week in great publicity.

A clergyman who was a dipsomaniac of the solitary class, and drank for a week or more in seclusion, among strangers, had abstained for two years. He was called to a rich church in New York, with the most flattering prospect, and on the day of his installation he disappeared, and was found wildly intoxicated in a distant town.

These cases are not uncommon in medical observation, and are not easily explained by any theories of the present. Such persons who are known to have drink paroxysms are still rated as persons of average ability, and capable of acting sanely, consistently, and with good judgment. Physicians in court-rooms swear that such men are fully sane and responsible, and that the drink paroxysm is a transient weakness, which could be overcome at will. This feeling is fostered in

the pulpit and temperance meeting, and these strange insane acts of dipsomaniacs are called moral lapses and obsessions of the evil one, that can be exorcised and driven out at the will of the victim. This is the fatal delusion which permits these cases to go unrecognized and to occupy places of trust and confidence, with continuous and certain failures. It is a startling fact that capital and practical experience has passed far beyond the theories of to-day, both anticipating and unconsciously confirming the most advanced facts of scientific research.

The dipsomaniac and even the moderate or excessive drinker is regarded with suspicion. His capacity, both mental and physical, is considered dangerous in all positions of trust and responsibility. Corporations, railroad companies, and capital everywhere, require total abstainers and are growing more reluctant to employ men who have even the suspicion of being inebriates or dipsomaniacs, irrespective of all skill or ability they may possess. Many railroads discharge workmen who are seen in saloons. Mercantile agencies and insurance companies estimate the capacity and longevity of a man on his history as a total abstainer. In this there is no theory, only experience of the danger of trusting men who use spirits. I think it is true that in many communities there are dipsomaniacs occupying places of trust, as managers of public interests, as professional men, as business men, who are known to have drink paroxysms at times, but in the intervals they are trusted. By and by a series of disasters take place and serious suffering and losses follow, which are attributed to other than the real causes.

The defaulter, the trusted man who wrecks his business; the clergyman or physician who become involved in some great wrong; the judge or lawyer who proves recreant to his trust; the men or women of previous good character, who commit overt acts that astonish the community; the many instances in which great defects of judgment and common-sense appear, not noticeable before in such cases, are in many instances clearly traceable to dipsomania.

These drink paroxysms are always destructive to the higher brain centres. The capacity to reason soundly and consistently is continuously diminished. The brain cells become more unstable, the senses more faulty and imperfect, and the power of co-ordination and discrimination weaker. A literal paralysis, beginning in the highest brain functions and extending down to the lower centres, is present. A clinical study and examination of the higher brain manifestations in these cases furnish ample confirmatory evidence of this statement. It should be remembered that in these cases two conditions are present. One a defective brain organization in a process of degeneration, the other the effects of a paralyzant drug whose action on a healthy brain still further precipitates degeneration. The impulsive, irresistible demand for the narcotism of spirits is a symptom of this condition. The chronicity of the case will depend on heredity and mental defects apparent before spirits are used. But the fact that at uncertain intervals narcotism from spirits becomes a mania which expends itself in distinct nerve storms is unmistakable evidence of unsoundness and disease. The impossibility of any one suffering from these attacks being healthy and of sound brain should never be questioned.

It is assumed in business circles that capital is in peril, and clear, sound judgment wanting in such cases, and why should public sentiment regard these persons with indifference? The facts are accessible in every case, and open to medical study and observation. The following is an illustrative case:

J. B——, a merchant, aged forty-six, had drink crises for seven years; from one to three attacks every year. Is at the head of a large business, and has many responsibilities and places of trust. He is regarded as a strong-minded man in public estimation. His family physician gives the following estimate of him: A gradual change of character and judgment has been going on for years. He has grown more emotional and excitable in his private life. He is depressed and angry at little things, afraid of public criticism, and greatly elated with praise. He is untruthful and slanderous at times, and denies memory of events that appear to reflect on his judgment. Grows more envious and exasperated with small dealers who are rivals. At times is meanly dishonest to his help and then extravagantly generous. Has changed his religious faith three times in four years, also his political faith. He is at times the supporter of strange theories. At one time he was a violent temperance man, then he urged free license, and beer-houses wherever asked for. After a drink paroxysm he is sceptical and dishonest, treats everyone with rudeness, and tries to take advantage. Before the drink craze he is just the opposite and extremely credulous. His pride of appearance, and his business integrity are lowered, and the ability to concentrate his mind on any topic long is lost. Physically an irritable heart, enlarged liver, with attacks of indigestion, and insomnia are present. He has made several wills in the course of two years, and his family are greatly distressed at his changed conduct, and changeable feelings. In his business he is much the same, deferring to others at times more than usual, but otherwise giving little evidence of change.

Recently I was consulted concerning a similar case of a dipsomaniac who in public life was considered a strong, vigorous man, but in his family circle was so irritable as to be delirious and unreasonable to a degree that was unbearable. His drink period was the only quiet season in his family circle. Close study of his public life showed a marked failure of both reason and strength.

Another similar case occupies a very responsible position, but so far he defers to others on all matters of importance. But at any time he may insist on carrying out some faulty, insane reasoning, to the loss and suffering of many. Physicians who are called to advise in such cases should take clear, broad views, along scientific lines, above all theories or popular notions. There should be no hesitation in the recognition of unsoundness and degeneracy in all such cases. A man with drink paroxysms is essentially one of weak, defective judgment, and not only unbalanced, but unstable, untrustworthy, and liable at any time to be possessed with morbid impulses, not only for spirits, but in other directions equally abnormal. The dipsomaniac is always over the line of sanity, always abnormal, strange, erratic, foolish, cruel, or criminal. Dementia, mania, paresis, epilepsy, are all before him, and are sure to follow, unless some acute disease terminates the case in some other way.

Dipsomania should be recognized practically by all medical men, and treated in a clear, vigorous way.

A Horrible Habit.—An esteemed contemporary has this to say about the smoking of cigarettes: "It subserves avarice, deludes ignorance, preys upon weakness, panders to vice, depletes the purse, enfeebles the mind, and destroys the body; and is a sin toward God, an outrage upon nature, and a curse to mankind." Gracious!

A Newly Discovered Foramen.—Dr. J. W. Hartigan, Professor of Human and Comparative Anatomy in the West Virginia University, informs us of his discovery of a foramen in the base of the transverse process of a lumbar vertebra in the human subject. This, he says, has never been noticed by any anatomist, so far as he is informed. Henle's case was one of union, by a bridge of bone, of the mammillary and accessory processes, an entirely different thing.—*New York Medical Journal.*

ANTITOXIN IN THE TREATMENT OF DIPHTHERIA IN YONKERS, N. Y., AND THE RESULT.

By VALENTINE BROWNE, M.D.,

PRESIDENT OF THE BOARD OF HEALTH AND HEALTH OFFICER; CONSULTING PHYSICIAN TO ST. JOSEPH'S HOSPITAL, AND PHYSICIAN TO THE ACADEMY OF MOUNT ST. VINCENT, ETC.

SINCE the introduction of antitoxin serum in 1890 a new and very important change has taken place in the treatment of that most fatal of juvenile diseases, diphtheria. Owing to the failure of Koch's tuberculin in 1891, much caution has been properly exercised in the practical application of the new remedy. Now, however, after repeated experiments by men of reliable scientific ability and the actual practical application of this most important discovery, there seems to be no well-founded objection to its use. It is hardly necessary to add the fact that antitoxin serum was a very scarce article in the United States until recently, and consequently was not available to any practical extent until the latter part of 1894, and indeed the first consignment consisting of one vial reached Yonkers late in the month of September last, and the supply continued very limited until the latter part of January of the present year. Since the beginning of February, however, the supply has been nearly equal to the demand, and as a result the mortality from diphtheria has been wonderfully reduced. For example, during the year 1891, the mortality from diphtheria in Yonkers was fifty per cent. of those who suffered from the disease; in 1892, fifty per cent.; in 1893, it was 47.36 per cent; and in 1894, when antitoxin was employed to a limited extent, the death-rate was reduced to 34.09 per cent., while in January, 1895, the mortality dropped to 16.66 per cent., and for the two months ending March 31st, the death-rate was still further reduced to 12 per cent.

It will thus be noticed that a remarkable saving of human life has been accomplished in this little city through the use of antitoxin, not only by its curative effects, but also by its potency in protecting or immuning children exposed to diphtheria.

I will now briefly relate my individual experience in the use of antitoxin, and will submit the following typical cases for consideration:

CASE I.—J. N——, aged four. Saw the patient in consultation with Dr. Wolf, October 30th at 3 P.M. The doctor informed me that the child was taken ill in the morning of October 28th and that he saw the patient that evening, when he observed a patch of membrane on the left tonsil and notwithstanding active treatment the child became rapidly worse, with considerable extension of the diphtheritic membrane to the larynx, etc.

At my first visit the temperature was 103.5° F.; pulse, 120; respiration, 28; voice husky, face pale, breath fetid, difficult deglutition, urine scanty and one-quarter albumin. I advised the use of antitoxin, and at 5 P.M. same day administered 5 c.c. of Behring's antitoxin No. II. Saw the child next morning at 11 A.M., and found all symptoms about the same as those of the previous day, except the urine, which was one-half albumin. We now repeated the injection, 3 c.c. of antitoxin, and employed appropriate treatment for the kidney complication. Saw the child next day, November 1st, 11 A.M. Temperature, 100° F.; pulse, 90; respiration, 22. Membrane disappearing; had four hours' sleep during the night; but the urine was almost suppressed and three-quarters albumin.

November 2d, 10 A.M.—Rested well during the night; membrane missing; temperature, pulse, and respiration, normal.

November 3d.—Had a restless night, passed some urine, albumin slightly diminished, takes nourishment better.

November 4th.—Patient much better apparently, but the urine is nearly solid.

November 5th.—Nephritis worse, patient semi-comatose.

November 6th.—Uremic convulsions terminated the life of the little patient at about 3 P.M.

CASE II.—October 31st called to see M. C——, aged eight. Patient fairly well nourished, complained of headache on the previous day; some difficulty in swallowing. Temperature, 102° F.; pulse, 109. Some difficulty in breathing, and a diphtheritic patch about the size of a five-cent silver piece on right tonsil; slight hoarseness; urine, normal. Prescribed the usual remedies. Called the next morning at 9 A.M. Found the patient very restless. Temperature, 103° F.; pulse, 118; breathing embarrassed, anxious expression of features, difficult deglutition, right tonsil and posterior wall of the pharynx covered with a grayish-white membrane, hoarseness more marked, croupy cough. Procured a culture for examination. Administered 5 c.c. of Behring's antitoxin No. II. Discontinued all forms of internal and local treatment except stimulants. Called again the same afternoon at 5 o'clock, found no abatement of symptoms; stimulants increased. Saw the patient again at 9 P.M. Slight improvement noticed. Injected 10 c.c. of Behring's No. II. antitoxin. Called the following morning at eight o'clock and found the patient much better. Had three hours' sleep during the night. Temperature, 100° F.; pulse, 90; stridulous breathing had disappeared; membrane diminishing and discolored; general condition much better.

November 2d, 9 A.M.—Patient still improving; anxious to get up. Temperature and pulse normal, breathing normal, and hardly any diphtheritic membrane visible. Stimulants discontinued.

November 3d.—Patient rapidly improving; no complication.

November 4th.—Continues to improve and is feeling almost perfectly well. Microscopical examination of cultures revealed an abundant supply of Klebs's bacillus. Patient anxious to return to school; is perfectly well.

November 7th.—No return of any symptoms of diphtheria; no reaction from antitoxin. Patient well.

CASE III.—November 6, 10 A.M. N. G. F——, aged four years and three months, had been sick thirty-six hours, the glands of the neck were much enlarged, tonsils red, large, and inflamed, right tonsil and uvula nearly covered with diphtheritic membrane. Considerable exudation in both nasal cavities. The face was pale, and there was a perceptible fetid odor from the breath; skin, hot and dry. Temperature, 103 1/8° F.; pulse, 140; respiration, 30 per minute. Immediately injected 5 c.c. Behring's antitoxin; directed to wash the mouth, etc., with a solution of salt in water by means of a fountain syringe; every three hours milk and brandy, etc.

November 7th, 9 P.M.—Patient rather worse; temperature, 104° F.; pulse, 148; respiration, 33. Membrane extending into the larynx; croupy breathing. Injected 10 c.c. Behring's antitoxin. Called in the afternoon at four o'clock. Patient no better. Temperature, pulse, and respiration showing no improvement; some hemorrhage from nose. Injected 5 c.c. antitoxin. At 10 P.M. found the little patient brighter. Temperature, 102 3/8° F.; pulse, 120, and strong; respiration, 26. Stimulants continued.

November 8th, 9 A.M.—Temperature, 100° F.; pulse, 90; respiration, 24. General condition improved and takes his nourishment freely. Stimulants continued. 8 P.M. Temperature, 99° F.; pulse, 88; respiration normal; membrane nearly gone.

November 9th, 9.30 A.M.—Temperature, pulse, and respiration normal. No diphtheria membrane visible; stimulants discontinued. Heart, lungs, and kidneys normal.

November 10th.—Patient continues to improve, no reaction from the injections of antitoxin.

November 12th.—Patient sitting up, apparently well.

Case IV.—November 13th. W. W——, aged ten years, school-boy, sick one day before my first visit. On examination a patch about the size of a dime piece was observed on the left tonsil; pulse, temperature, and respiration slightly above normal. Prescribed iron internally and salt solution locally and a generous milk diet.

November 14th, 10 A.M.—Temperature, 101° F.; pulse, 106; respiration, 26. With much extension of the diphtheria membrane, involving the uvula and right tonsil and extending into the pharynx, the nasal cavities were also involved, and the general condition of the patient was much worse. I now injected between the shoulders 10 c.c. of Behring's antitoxin. Called again at 5 P.M., and found some improvement and no extension of the exudation.

November 15th, 9.30.—Membrane becoming detached, removed a piece nearly the size of a ten-cent piece from the right tonsil, and a good-sized plug of membrane from the nose. Temperature, 99.75° F.; pulse, 86; respiration normal.

November 17th.—Patient says he is perfectly well and thinks he should be allowed to prepare for school.

November 20th.—Called again and found my patient out of bed and perfectly well, no return of any abnormal symptoms, no reaction from the antitoxin.

Case V.—November 29th. F. C——, female, aged seven; school-girl. On November 28th she complained of a chilly feeling and headache while at school in the morning, remained home that afternoon and became rapidly worse, and when I saw her first her temperature was 101.5° F.; pulse, 114; respiration, 26. Both tonsils and posterior pharyngeal wall were covered with false membrane, accompanied by much difficulty in swallowing anything. I at once injected 10 c.c. of Behring's antitoxin No. II.; ordered gargles of salt and water, milk, but no stimulant or other internal treatment.

November 30th, 9.30 A.M.—Patient better. Temperature, 100° F.; pulse, 100; respiration, 20. The patient, however, developed some diphtheritic bronchitis, for which appropriate treatment was employed.

December 1st.—The diphtheritic membrane very much diminished and discolored. Bronchitis more marked. Temperature, 101⅛° F.; pulse, 104; respiration, 26; urine normal; heart sounds normal.

December 2nd, 10 A.M.—No return of the exudation; general condition of the patient much like that of yesterday.

December 5th, 6th, and 7th.—Not much change to note.

December 8th.—Bronchial inflammation yielding. Temperature, 100° F.; pulse, 98; respiration, 22.

December 10th.—Patient much better, but prostrate.

December 12th—Continues to improve and is anxious to get up.

December 14th.—No reaction from the antitoxin; patient well, but still suffering from prostration. A generous diet and tonics directed.

December 20th—Last visit, patient well.

Case VI.—December 14th. J. McC——, aged nine years and six months. The mother noticed a barking cough the day before my visit, which became worse during the afternoon and evening, when she used some domestic remedies which on previous occasions she said cured the croup. On examination there was noticed only slight redness of tonsils and uvula, no membrane visible, no swelling of the glands of the neck. Temperature, 99⅞° F.; pulse, 100; respiration, 16, and labored, both in inspiration and expiration; pupils dilated; anxious expression of countenance; cadaverous color of face; traces of albumin in urine.

Diagnosis: Membranous croup, possibly diphtheritic in character. I at once procured a culture from the vicinity of larynx and submitted it for examination. Prescribed the usual remedies for croup. Called at 6 P.M. same day, found the patient very much worse, with evident signs of impending suffocation, the nares were plugged with false membrane and the exudation seemed to extend down the larynx, probably invading the trachea. I now injected 10 c.c. Behring's antitoxin. Whiskey, digitalis, and nux-vomica every hour in small doses.

December 15th, 8 A.M.—Patient passed a very restless night. No sleep until about 5 A.M., when the symptoms became less urgent and one hour's sleep was procured. At my visit, however, the respirations were still sibilant, surface cool, pulse rapid and feeble, countenance pale and livid, heart action rapid but feeble; treatment continued, with increased stimulants. Called at 3 P.M. same day. All symptoms worse; constant tossing and plunging of patient. Refuses all nourishment and medicine. Prognosis grave. I now requested a consultation, and suggested intubation as a last resort; but the mother would not submit, saying: "A neighbor's child died after forcing that thing into his throat, and if the child was going to die he will die anyhow;" and for the same reason a consultation was refused. I now injected 25 c.c. of antitoxin as prepared at the Pasteur institute (Roux's formula), and directed emetics of turpeth mineral occasionally, and whiskey per rectum; digitalis and nux vomica hypodermically. Called again at 10 P.M. same evening, expecting to find my little patient dead, but to my surprise found him very much relieved, all the distressing symptoms having decreased and the patient breathing rather freely and now takes his milk and whiskey.

December 16th, 9 A.M.—Patient rapidly improving. Slept four hours during the night. Vomited several pieces of membrane in the early morning, since when the breathing was almost normal. Temperature and pulse normal, as it was throughout the attack. Report from culture examination "abundant diphtheria bacilli."

December 17th.—Patient still improving. The act of vomiting cleared not only the larynx and trachea, but also the nares, of all detached membranes, and the breathing was perfectly normal.

December 18th.—Patient most anxious to leave the bed. Says he must go to school, although he is still weak. No return of former symptoms, nor reaction from the antitoxin.

December 20th.—Still improving and seems well.

Case VII.—December 27th. F. M——, aged ten months; sick two days previous to my visit. Child poorly nourished. Temperature, 101° F.; pulse, 120, and weak; respiration, 28. Left tonsil covered with a yellowish-white membrane; slight bronchial trouble; urine normal. Having Pasteur's antitoxin with me I injected 10 c.c. at 11 A.M. Called at 4.30 P.M. same day and found the temperature, pulse, and respiration slightly improved. Moderate stimulants ordered; salt and water wash for the mouth and nasal cavities.

December 28th.—Patient not much improved. Injected again 10 c.c. Pasteur antitoxin, and increased stimulants.

December 29th.—My little patient better. Is nursing well; membrane nearly gone, moderate stimulation continued. No other internal treatment.

December 30th.—Child very much better; but the back and chest covered with a rash very much like nettle-rash. Called four days later and found my little patient well and the erytheme all faded away.

Case VIII.—F. W. N——, aged four. Has been unwell for two days. The glands of the neck were enlarged; tonsils red and œdematous, with slight exudation on left side. Temperature, 100° F.; pulse, 110; respiration, 26. Painful deglutition. Prescribed the usual remedies. Called at 4 P.M. same day.

December 28th.—Child growing worse. The breath was offensive, and indications of a grave case were well marked. I now injected 15 c.c. of Pasteur's antitoxin, discontinuing all other internal treatment, the child being unmanageable.

December 29th, 9 A.M.—Child much improved.

Temperature, 99° F.; pulse, 96; respiration normal. Membrane discolored and diminishing.

December 30th.—Patient continues to improve. Temperature and pulse normal. Only a small portion of membrane visible.

December 31st.—No trace of the exudation visible.

January 2d.—Child steadily improving; no reaction.

Case IX.—J. M——, aged six years, complained of frequent chills, nausea, and vomiting three days previous to my visit, January 6, 1895. These symptoms were accompanied by severe headache and hemorrhage from the nose. No enlargement of the glands and no difficulty in swallowing; but, as the mother put it, the child became very stupid. On examination I found the soft palate and posterior wall of the pharynx covered with the characteristic membrane. Temperature, 98.75° F.; pulse very rapid, wavy, and compressible; skin cool and clammy; face pale; tongue dry and the odor from the mouth most offensive. The patient drowsy and almost comatose; heart sounds weak and irregular. Urine one-eighth albumin. Prognosis very unfavorable. At 10.30 A.M. I injected 15 c.c. of Pasteur's antitoxin, also a hypodermic of digitalis, tincture nux vomica combined with whiskey; hot-water bags, bottles, etc., to the feet, hands, and in fact to all parts of the body. Called in again at 11.30 A.M., at which time a slight improvement in the character of heart and pulse was perceptible. I now repeated the hypodermic of digitalis, nux vomica, and whiskey and directed stimulants every half hour and frequent cleansing of the mouth. Called again at 4.30 P.M., same day and found the patient in a semi-comatose condition. Repeated the hypodermic, and continued the hot applications and stimulants. At 10.40 P.M., same day, the temperature was 99.75° F.; pulse, 98, and improved in regularity. Hypodermic repeated, and the extremities being now warm the hot applications were removed and stimulants continued. At 12 midnight found my little patient still in a critical condition, although, owing to the stimulants, the circulation was somewhat improved.

January 7th, 1 A.M.—I injected 25 c.c. of Pasteur's antitoxin. Called at 8 A.M. same day and found the patient, to my surprise, better, with a temperature of 100° F.; pulse, 102, full and regular. General condition improved. Membrane discolored and slightly detached. Stimulants, digitalis, and nux vomica continued. 3 P.M.: Improvement continues; takes nourishment freely. 8.30 P.M.: Temperature, 101° F.; pulse, 98; respiration, 22; epistaxis, etc. Administered 10 c.c. antitoxin.

Called next morning at 8.30. Patient was restless and unmanageable during the night until 3 A.M., at which time he dropped into a sound sleep which lasted four hours; woke refreshed and much improved. At my morning visit the temperature and pulse were normal, membrane shrunk and very much diminished. Continued the stimulants, digitalis, etc.

Called next day at 9.30 A.M. Patient still improving and all traces of membrane absent. No reaction from the antitoxin.

January 12th.—Made my last call, patient well.

Case X.—G. ——, aged two and a half, female; bottle-fed; scrofulous tendencies. Examined the child January 10, 1895, and observed the following condition: Temperature, 100° F.; pulse, 92; respiration, 20; glands enlarged; tonsils swollen, the left tonsil and soft palate dotted with a yellowish-white deposit; fetid odor from mouth. This child had been ill for two days previous to my visit. Diagnosis, diphtheria, and having antitoxin with me I at once injected 5 c.c. Behring's No. II. No other treatment except stimulants and frequent cleansing of the mouth, etc.

January 11th.—Patient better; temperature, pulse, and breathing improved.

January 12th.—Membrane disappearing.

January 13th.—No membrane visible; tonic treatment ordered.

January 15th.—Child is well; no reaction from use of antitoxin.

Case XI.—A. C——, aged seven. Saw the child January 16th. While attending school, three days previous to my visit, the teacher noticed the boy looking ill, and immediately sent him home. He now complained of a headache, sore throat, nausea, and occasional vomiting. Temperature, 102° F.; pulse, 68; respiration, 18, and of a wheezing almost whistling character. Face rather flushed; eyes protruding; and an extreme restless condition, tossing from one place or position to another, grasping at imaginary objects, etc. The tonsils, soft palate, and pharynx inflamed, but no membrane visible. The voice hoarse, muffled, with a very troublesome, dry, hacking sort of cough. Inspiration and expiration very difficult; the superclavicular and intercostal regions retracted with each respiratory effort. Prognosis: No hope of recovery. However, 10 c.c. of Behring's serum was injected. Stimulants, digitalis, and nux vomica hypodermically, the heart sounds being weak and irregular. Saw the patient again that afternoon at three o'clock, seven hours after the administration of antitoxin; patient no better. Called again at 8 P.M. All symptoms more grave, membrane probably extending into the trachea and bronchi. Stimulants increased to the utmost limit, emetics of turpeth mineral to prevent if possible the impending suffocation. Fifteen cubic centimetres of Gibier's antitoxin injected. Called next morning at seven o'clock, and found the little sufferer apparently dying. Cyanosis very pronounced and breathing almost impossible, clutching at everything in view. Hypodermic injection of a mixture composed of five drops of tincture of digitalis, five drops of tincture of nux-vomica in brandy was now employed, and 25 c.c. of Gibier's antitoxin was injected. The throat was now again examined, as it was yesterday. But at this examination I observed what seemed to be an exudation on the posterior wall of the pharynx. I now left my little patient to die, as there seemed no hope for him; requested the family to let me hear from him if living at noon.

Not hearing from my patient up to 1 P.M., I visited him once more, and to my surprise found him somewhat relieved. Treatment continued. Saw him again at 10 P.M.; repeated the hypodermic of digitalis, etc. Called the following morning at nine o'clock; found my patient still improving, the face less cyanotic, breathing better, and temperature normal, but the membrane, which seemed to have extended from the larynx upward to the fauces, still present. 5 P.M.: Improvement still continues, the deposit of the pharynx and soft palate diminishing, but the patient still very much prostrated. Stimulants, etc., continued.

January 19th, morning.—Passed the night without any return of unfavorable symptoms, had three or four hours' sleep. Takes nourishment better, but there is still much prostration present.

January 20th.—No membrane visible. General condition improved.

January 22d.—Well.

Case XII.—January 26th. Female, aged eight months. Had been ill three days. Had all the symptoms of septic poisoning. Temperature, 98.25° F.; pulse very rapid, thready, and extremely feeble; cardiac sounds feeble and irregular; urine albuminous; dyspnœa; soft palate, tonsils, uvula, and nares lined with membrane; cold clammy skin, etc. Told the parents that the child was beyond all hope of recovery; but they implored me to use the new remedy. At 11 A.M. injected 10 c.c. Behring's serum. Directed hot applications to the whole body, and administered a hypodermic injection of brandy, digitalis, and nux-vomica, the heart and kidneys being affected and the urine albuminous; also the use of antiseptic lotions, etc.

January 27th.—Morning call. Patient seemed a little better, 10 c.c. antitoxin injected. The other treatment

continued. Called in the afternoon at four o'clock and found, to my surprise, a marked improvement. Digitalis, nux-vomica, and brandy continued.

January 28th, 10 A.M.—Child still improving. Temperature, pulse, and breathing normal. Heart sounds muffled, with evidence of endocarditis and a systolic murmur; but all traces of the exudate gone, and the little patient crowing and apparently very much better. Digitalis, nux-vomica, etc., continued.

January 29th.—Child passed through the night nicely, except some troublesome breathing at my visit; there was considerable dyspnœa, and an examination of the chest revealed extensive œdema of both lungs, yet the little patient would sit up in its crib in spite of its mother.

January 30th, morning.—Patient gave vent to a few loud screams and breathed her last about five minutes before my visit.

Case XIII.—February 13th. Male, aged five. Second day of illness. To be brief, this patient presented every symptom of laryngeal croup and was cyanotic, in fact suffocating. Twenty-five c.c. of Pasteur's serum was injected at 5 P.M., hypodermic of digitalis, nux-vomica, brandy, etc., with directions to give an emetic of turpeth mineral when the symptoms of suffocation became very urgent. Called the next morning and found the child playing with its toys, and was indignantly informed by the mother that I made a mistake, her child had, as she said, no croup or diphtheria, and the only thing the matter with the child was a part of a goose quill it had in its mouth which accidentally slipped back and stuck in its throat, and the emetic, or as she said, the yellow powder, made him vomit up at midnight, since when he was all right. I then requested to see what the child vomited, but was told it was thrown into the fire and burned; I then asked her to describe the goose-quill vomited. She began by saying "that it was about an inch or more long, open at one end, and nearly closed at the other, and was a good-sized goose-quill, but a little soft because it was so long in the child's throat." I then, of course, tried to explain to her the nature of the vomited matter, but she would not be convinced, until her second child, aged two years, was prostrated with diphtheria. My goose-quill patient continued to improve, and in a few days was well, while his little brother had a pretty severe attack of diphtheria, but the exudation did not extend to the larynx; and the child made a good recovery in due time after one full dose of antitoxin. (Case XIV.)

Case XV.—March 20th. Saw this child, aged five, in consultation with Dr. Wolf. Tonsils covered with membrane; temperature and pulse abnormal; child poorly nourished, etc. Injected 6 c.c. Behring's antitoxin.

March 31st.—Child well.

And now to be brief in describing the remaining twenty cases up to and including all cases coming under my observation to April 1, 1895, I will merely make comparative statements.

Cases XVI. and XVII. were almost similar in symptoms and treatment to that of No. II. Cases XVIII. and XIX, much like No. XII. Cases XX., XXI., and XXII. like Case IV. Case XXIII. like Case V. Case XXIV. like Case No. VII. Case XXVII. like Case IX. Case XXIV. like Case X. Case XXX. like Case XI., except in the mode of invasion of the exudate, which in this case was from the trachea to the fauces. Cases XXXI., XXXII., XXXIII., XXXIV., and XXXV. were mild in character as compared to the first twelve cases, probably on account of the early use of antitoxin, it being employed in every one of these cases during the first twenty-four hours of the disease. The goose-quill before referred to was unquestionably a cast of the trachea, or perhaps of the bronchi, and although the symptoms strongly indicated membranous croup, yet a culture examination proved it to be diphtheria. While the last twenty cases which I have briefly referred to were not exactly like those with which they are compared yet the symptoms and course were so nearly like them that a separate description may be considered irksome to the reader.

The antitoxin treatment, you will observe, has been successfully employed in thirty-three out of the thirty-five cases in which it was used. Of the two deaths which occurred, the first (Case I.) I am convinced would have recovered were it not for the malignant nature of the acute nephritis with which it was complicated, and which, from all I can learn in shape of a history of its invasion, was more primary than secondary to the diphtheria. The second death (Case XII.), the child was in a moribund condition when I saw him and had been ill for three or four days. This delay, combined with the fact that the child was strumous, bottle-fed, and poorly nourished, rendered his case hopeless.

At least twenty of these thirty-five cases were of the class called malignant, and in my experience and practical treatment of upward of three hundred cases of diphtheria during the past twenty years, not less than fifteen of the twenty would have died in spite of the best-known treatment prior to the use of antitoxin. Ten of the remaining fifteen might perhaps have recovered without the serum, but when it is considered that I employed the new remedy only in cases which, in my opinion, presented grave symptoms (mild cases being treated without the serum), it is questionable whether or not even this number would have survived. Many of those cases presented symptoms of the most grave and fatal character, particularly those in which the larynx, trachea, or bronchi were involved, symptoms which convey a thrill of despair to the mind of the experienced physician and which tell him plainer than words that he is powerless in his efforts to stay the onward march of this most fatal disease. Intubation of the larynx was suggested in four of these cases, but refused. Tracheotomy was also recommended, with like result, antitoxin alone, under Providence, prevented the impending fatal termination of those cases. When there was any doubt of the clinical diagnosis a culture was procured and forwarded to Dr. Park for examination and in every case abundant Klebs-Lœffler bacilli were found.

There was no reaction in connection with the use of Behring serum except in two cases where a considerable advance in temperature was noted, but after the use of the Pasteur serum a mild form of erythema appeared in four cases in from twelve to twenty-four hours after the injection, lasting only a few days, then fading away leaving no unpleasant symptoms behind. The only objection I can name to the use of Pasteur's antitoxin is its bulky condition and consequently the large amount necessary for hypodermic injections, in other respects I found it very satisfactory.

The only internal or local treatment employed in connection with the serum was tr. nux vomica, tr. digitalis, and alcoholic stimulants internally and a solution of chloride of sodium locally, for irrigation of the mouth and nose; tincture of iron in a few cases. We know that intelligent nursing and good sanitary surroundings contribute materially to the successful treatment of diphtheria, and that the absence of those conditions plays an important part in the fatal termination of such cases. Twenty of these cases were children of the most dependent class, and came under my observation in my capacity as Health Officer, and in those cases intelligent nursing and good sanitary regulations were for the time out of the question. Six of my cases were followed by paralysis of a mild form, which gradually disappeared, and complete recovery followed. Four of my convalescents could not swallow nourishment for from two to four weeks after all urgent symptoms disappeared, due to paralysis, and were fed per rectum. The greatest caution was observed in sterilizing the syringe and in the use of antiseptics. The syringe employed was the Pasteur syringe, which held 25 c.c.

In conclusion permit me to say that I had very decided objections to the use of antitoxin in diphtheria, and it was not until convincing reports from well-known scientific investigators were published in the MEDICAL RECORD that I, with still some misgivings, ventured to employ the new remedy. Now it is needless to say that I am completely converted, and am at present a firm believer in its merits.

Since reporting the foregoing I have successfully treated five more cases of diphtheria with antitoxin, making in all forty cases and two deaths.

IS THE PRESENT LOW MORTALITY IN DIPHTHERIA DUE TO THE USE OF ANTITOXIN SERUM?

BY JOSEPH S. HEALY, M.D.,

KINGSBRIDGE, N. Y.

WERE we to accept the apparent results from the use of diphtheria antitoxin serum in the hands of numerous observers, we might be tempted to abandon all of our tried and well-known line of therapeutics, and trust the patient's life to the serum alone. However, the fiasco of Koch's lymph is of too recent a date to permit unchallenged the acceptance of the statistics furnished by the advocates of antitoxin serum at home and abroad.

My recent experience with diphtheria, while not very extensive, is insufficient to convince me that other factors are at work which have more to do with the low mortality than the serum. During the present winter I have treated fourteen cases of diphtheria where Lœffler bacilli were found in abundance. The majority of the patients living within the city limits, the diagnosis was confirmed by a bacteriological examination made in the laboratory of the city Health Board. Of these fourteen cases of true diphtheria, I used the antitoxin serum in but three, but did not dare trust to it alone.

My first experience with the serum was in the first week of December on a child aged sixteen months who contracted the disease from his brother, whom I was then treating by our ordinary methods. In this case there were laryngeal symptoms and considerable prostration. I injected the serum, furnished by the Pasteur Institute, which resulted in an increased prostration for the succeeding twenty-four hours, after which time improvement was marked and convalescence rapid; but the membrane disappeared no sooner than in the case of his brother, and the bacilli existed for two weeks after the injection. This being my second case of diphtheria during the recent epidemic I was more impressed with the apparent efficacy of the new remedy than subsequent experience warranted.

My second trial of the serum was in the case of a child aged eighteen months, where I again used the Pasteur serum without any apparent effect one way or the other, and, as in the preceding case, the bacilli were present two weeks after the injection. In my most recent case of diphtheria I used Behring's serum. The case was a very light one, but the fifth culture, taken five weeks after the injection, contained bacilli.

Of the eleven cases treated with our older methods, without exception they made as perfect a recovery as where the serum was used, and in but one instance were bacilli found after two weeks from the taking of the first culture, and in that single instance the mother thought it too much trouble to carry out the treatment and the patient recovered virtually without any treatment, but the bacilli existed for nearly two months.

As a prophylactic, the first injection I made was on my own person, using 7 c.c. of Roux's formula. For the first five days following, no symptoms of reaction developed. On the sixth day an intense pruritus occurred around the seat of injection. On the seventh day I was suffering from the most severe attack of urticaria I have ever witnessed, lasting a week, and at times almost making me frantic. Five weeks ago I again injected the equivalent of two hundred normal units of Behring's serum into my thigh, and in four days afterward suffered from another attack of urticaria, though not so severe as in the first instance. I have never had an attack of urticaria previous to these two.

In the case of a child aged fifteen months, whose nurse contracted the disease, a culture from its throat showing Loeffler bacilli, I injected Behring's serum. Two subsequent cultures, taken three days apart, contained the bacilli. The fourth and fifth cultures contained no bacilli. During this entire period absolutely no symptoms of diphtheria developed. I injected the serum into nine other cases who had been exposed to the contagion, all of whom escaped the disease. As to whether these people would have developed the disease had the serum been omitted is an open question.

The statistics furnished by the advocates of the serum therapy are very encouraging, but do they prove anything? These advocates apparently ignore the fact that epidemics of diphtheria vary greatly as to malignancy; also an epidemic malignant at its commencement loses its virulence after a time and the mortality drops accordingly.

Another factor appears to be bacilli associations. According to several careful observers, if the Loeffler were not associated with strepto- and staphylo-cocci the prognosis was excellent and recovery the rule; but where these cocci were present the mortality was very high. Have the serum advocates carried their observations to this point and demonstrated a low mortality where these cocci existed? If so, their statistics are enhanced in value, but I can recall no instance where this has been done.

It appears to me we are passing through a very low dip in the mortality curve, such as happens in the course of all endemic diseases, and if such is the case, the large majority of the patients will recover, providing no line of treatment is adopted which did harm. I say providing no harmful therapeutics are attempted, because I am convinced that many of these little patients might have recovered were it not for the too energetic treatment adopted, such as swabbing and brushing the throat, denuding the surface of membrane, leaving a raw surface presenting a new field for reinfection and further poisoning.

I am aware of the fact that in one hospital abroad, while using the antitoxin serum, the mortality was very low; the supply of serum being interrupted the mortality increased until a fresh supply of serum was available. This would apparently demonstrate beyond question that the low mortality was due to the serum; but were there no other factors at work when the serum supply was exhausted? What was their treatment of the patients at that time?

While the serum may be all that it is claimed to be from a therapeutic standpoint, I do not think the statistics furnished during the recent epidemic as valuable as they appear, and a far greater period of observation is necessary before the claimed value of the serum can be admitted as an established fact. I shall continue the use of the antitoxin serum wherever I can; carefully observing its effects, but until its value has been proven by far more crucial tests than have been made so far, I do not think we are justified in trusting the lives of our patients to it alone.

2856 BAILEY AVENUE.

A Testimonial to Sir Henry Acland.—Subscriptions are being received for a testimonial to Sir Henry Acland, upon the occasion of his retirement from the Regius Chair of Medicine at Oxford. It is proposed that this testimonial shall take the form of a provision for the increased usefulness of the Sarah Acland Home for Nurses, an institution named after his late wife.

ANTITOXIN IN DIPHTHERIA.

By J. C. DAVIES, M.D.,

EMMETSBURG, IA.

THE reports thus far appearing in the MEDICAL RECORD on the antitoxin treatment of diphtheria are chiefly from the city hospitals. Having seen few cases reported in general practice, I have ventured to submit the subjoined report embracing the results of 21 cases treated with Behring's antitoxin, without a single death. Of this number 7 were under five years of age, 4 between five and eight years, 2 between eight and twelve years, 4 between twelve and sixteen years, and 4 were adults. Nine were affected in a severe form; of this number 4 were under five years of age, 2 under six years, and 3 under twelve years of age. In the remaining 12 cases the disease never reached a severe type, though their ages ranged from infants two years old to fifty-two years. Six cases were completely immunized after direct exposure, and no diphtheritic symptoms developed.

In 6 cases the antitoxin was given with the earliest manifestation of the disease, or within twenty-four hours after the appearance of the membrane, and in each instance the disease was either aborted or so modified that its course was comparatively light.

Of the 9 severe cases none were seen till the disease had progressed from the third to the seventh day. The disappearance of the membrane and subsidence of all active symptoms were complete in from two to three days. In 9 cases a mild rash, unaccompanied by any irritation of the skin, appeared over the face, neck, and some portions of the body, and, with one exception, disappearing the same day. In 1 case the rash persisted for about eight weeks without any noted results. In 3 cases there were marked renal complications with sharp albuminuria, and in 1 case, a boy four years of age, paralysis of the velum with bronchial inflammation and tedious convalescence.

The maximum amount of antitoxin used in any one case was 10 c.c. of No. 2, with 8 c.c. of No. 3 in a boy fourteen years of age. The minimum amount used was 4 c.c. in the smallest children, for immunizing purposes; number of doses in any single case, 3. The place selected for injecting was the interscapular region, the instrument used a large hypodermic syringe. No abscess or induration followed the introduction of the needle, which was always carefully cleaned in absolute alcohol after first washing with warm solution of boracic acid. The contents of a vial from which there had been used about 4 c.c. two months before, and which had twice been frozen solid subsequently to its having been opened, was used successfully in the case of a boy, four years of age, on the fourth day of the disease, and while it did not suffice entirely to remove all the membrane it arrested the progress of the disease until the arrival of a fresh supply a few days later, thereby saving the little patient's life. I mention this simply to show that neither two months' time nor the freezing to which it was twice subjected destroyed its therapeutic value. This was a severe case and the only one followed by paralysis. In one case of laryngeal diphtheria, in a girl twelve years of age, the symptoms promptly disappeared, although the case had reached an alarming stage before the administration of the antitoxin.

In all cases where the disease had made any considerable progress before the administration of antitoxin, alcoholic stimulants, together with iron and quinine, were given in connection with it; with the exception of the case of paralysis mentioned in the small boy, all recoveries were complete and uneventful. No cultures were made, as in two of the families there were several deaths before the administration of antitoxin. And, furthermore, exposures to these earlier cases resulted in at least seven other fatal cases in the adjoining country.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, April 27, 1895.

OUR DUTY IN ABORTION CASES.

THE report of the censors of the Medical Society of the County of New York, made on Monday evening last, considers the course to be pursued in cases of abortion requiring medical aid from reputable practitioners. The necessity for some definite understanding of the subject has become apparent in view of the arrests from time to time of respectable physicians who in their regular practice have been summoned to patients in extremis the victims of criminal operations by professed abortionists. More particularly, however, the said report became imperative in view of a recent case formally brought to the attention of the Society and to which we had occasion to refer at the time. Our comments were based upon our obligations as physicians to comply with the law, and thus insure for ourselves that protection, which as good citizens and willing helpers of suffering we had a natural right to obtain. The censors after a deliberate discussion of the fundamental questions at issue substantially agree with the principles as advocated by the MEDICAL RECORD.

It is very properly maintained in the report that the physician is morally bound to attend any patient in the capacity of medical attendant, irrespective of the character of the individual requiring his assistance. This is an obligation founded on the law of ordinary humanity. When granting this, however, the physician owes it to himself and his reputation to make use of all the means of legal protection against complicity in any criminality. This duty is forced upon him by the circumstances that surround him. He is virtually on the defensive rather than the offensive side of the argument. The common law and the articles of the Penal Code take precedence of the ethics of his own profession and the necessities of the situation absolve him from any endeavor to uphold the code of a class against the statue of a state. The power of deciding rests legally with those who have the right to enforce it, whether the law giving that power is or is not just.

In reference to the question whether or not a physician should divulge any information obtained from the patient, and which may be necessary under the circumstances "to enable him to act" as medical attendant the censors very properly are non-committal leaving debatable points to such interpretation as may be necessary for self-protection. In attempting to define the

position of the physician in these cases the censors endeavor, ingeniously, if not successfully, to draw the line between the really criminal, and the properly professional aspect of the situation. The report says although the law requires that a physician should divulge nothing he has learned in the capacity of a physician "necessary to enable him to act," the method of treatment in these cases is in no wise affected by a knowledge that the cause of the trouble was criminal or not. This may tend to quiet his professional conscience, but does not absolve him from legal responsibility. The simple fact is, the law requires that in all doubtful or suspicious cases he must make a report either to the Coroner or the Health Department. This is the beginning and end of the whole matter; he can put what construction he pleases upon the purely professional aspect of the question, but he must conform to the law, whether he believes in it or not. In this regard, as numerous cases have proven, he cannot afford to take any risks. All individual responsibility is offset by the superior and overwhelming obligations which the common law impose. The censors very properly believe in such a construction, and recommend that the attending physician give its interpretation the freest possible liberality in the interests of his personal safety.

The assertion in the report that there is no crime in failing to report a suspicious case when death does not take place may be open to question. Indeed we hardly think its validity would stand in a test case, inasmuch as the law contemplates punishing attempts at abortion, either directly or indirectly by the patient herself or the operator. The best method of reporting these cases as suggested by the committee is similar to that advised by the MEDICAL RECORD. The preference of course should be for a medical coroner, whose professional duty under the circumstances would be to gather the necessary evidence independent of that given by the physician and not unnecessarily implicate the latter before the public or a jury in an alleged violation of professional obligation.

The advice to take to such cases a consultant or other medical witness is reasonable and necessary, and will commend itself to everyone called to a suspicious case, wherein operative or other treatment may be urgently necessary.

PRESCRIPTIONS IN LATIN.

MANY innocent persons, says the New York *Times*, have died before their time because doctors persist in making out their prescriptions in what passes for Latin. The latest victim of this habit is a baby three months old, the son of an East Side tailor named Cohn. The child had a cold, and Dr. Herman Jarecky, who was called to attend him on Sunday, made out a prescription which, when filled, was to contain, among other ingredients, three drams of castor-oil. The doctor did not write "castor-oil," but "Ol. Ricini."

The drug-clerk used "oleum pini" instead of "oleum ricini," and two doses of the medicine killed the baby —so says the *Times*. The editor thereupon attacks, with the usual arguments, the practice by physicians of using Latin in writing their prescriptions.

However correct the critic may be, his present illustration of the alleged evils of Latin is unfortunate. There is no such thing in our dispensatories as *oleum pini*. There are *oleum pini foliorum* and *oleum pini sylvestres foliorum*; and if these drugs had been indicated the prescription could have been understood in any part of the civilized world. The baby did not die therefore because the prescription was written in Latin. The essential fault and danger in prescription-writing after all is bad and careless writing by the doctor, and hasty reading by the druggist. We do not see how changing the prescriptions into vernacular would help matters, and it would make infinite confusion and trouble to students of the literature of therapeutics.

The teachers in our colleges ought to teach prescription-writing with more care, and that will prove a simpler and more effective remedy than writing prescriptions in Latin.

THE FATAL FOOTBALL.

EVERY season we hear much of football casualties, and of the brutality of certain noted players. The newspapers have a standing head-line, "Football Casualties," and the popular belief that the game is a dangerous one is almost universal. Yet some defenders of the sport contend that this general condemnation is unjust, that we hear of the few accidents, just as we do of other exceptional occurrences, but that the great numbers of games that are played without incident or accident pass unnoticed. In the recent annual report of the Board of Visitors to the Military Academy at West Point the Committee on Hygiene and Athletics presented some statistics which would show that the opponents of football as it is now played have reason on their side.

From a study of some tables prepared by Dr. Harvey from the hospital records for two periods of three months each in 1892 and 1893, the following figures were obtained:

Football injuries	91
Injuries in riding-hall	45
Injuries in gymnasium	19

But this is by no means a fair comparison, for there were but 61 football players, while those under instruction in the riding-hall numbered 382, and those in the gymnasium 207. Furthermore, football was played but once a week, while the riding exercises took place three times a week, and those in the gymnasium six times. Finally, the football injuries were, as a rule, more severe than those sustained in the riding-hall or gymnasium.

"So far as we know," the Committee reports, "this is the first contribution of accurate comparative data of these three forms of athletics in the same institution, under identical surroundings and by the same class of men. If the frequency of gymnastics (six times a week) of riding (three times a week), and of football (once a week) are taken into account it shows that per man playing there were respectively from about twenty to over one hundred times as many accidents in football as in the riding-hall and in the gymnasium, and that the gravity of the accidents as measured by the number of days lost per man playing or per man injured, or by

the number of men off duty per diem, is vastly greater from football than from either of the other two forms of athletics."

These figures are most instructive and speak loudly in favor of the proposed amendments to the rules, whereby the "mass plays" and other of the more dangerous features of the game are to be done away with. Unless such changes are made, popular opinion is likely to demand that football be suppressed by law, and put on the same level as the prize-ring.

News of the Week.

The Illinois State Board of Health.—The Faculty of the Northwestern University Woman's Medical School of Chicago recently passed resolutions of regret that the State Board of Health had seen fit to grant a license to practise to students of the college who had failed to pass the graduating examination. The State Board was requested to make its standard of qualifications at least as high as that of the best medical college in the country.

The American Academy of Medicine will meet in Baltimore, Md., on Saturday, May 4th, and Monday, May 6, 1895, under the presidency of Dr. J. McF. Gaston.

The Association of American Medical Colleges will hold its sixth annual meeting at the Rennert Hotel, Baltimore, Md., on Wednesday, May 8th, at 2 P.M. It is rumored that an attempt will be made at this meeting to recede from the action taken a year ago providing that "graduates of later date than 1898 be required to furnish evidence of attendance upon four years of medical lectures, in different years, of not less than six months' duration each." It is greatly to be hoped that this attempt will be unsuccessful.

Dr. Elon J. Lawton died in Rome, N. Y., on April 18th, of apoplexy. He was born sixty years ago. He was for many years coroner of Oneida County, and for the past five years was an alderman of the city.

Association of Acting Assistant Surgeons.—A special meeting of the Association of Acting Assistant Surgeons of the United States Army will be held in Baltimore, Md., May 8th, during the coming session of the American Medical Association.

Association of Military Surgeons of the United States.—The fifth annual meeting of this Association will be held in Buffalo, N. Y., on May 21, 22, and 23, 1895. In addition to a number of addresses, the preliminary programme contains the titles of thirty-three papers on subjects relating to military surgery. The officers of the Association are: *President*, George M. Sternberg, Brigadier-General and Surgeon-General, U. S. Army, Washington, D. C.; *First Vice-President*, Louis W. Read, Colonel and Surgeon-General, National Guard of Pennsylvania, Norristown; *Second Vice-President*, Albert L. Gihon, Medical Director, U. S. Navy, Washington, D. C.; *Secretary*, Eustathius Chancellor, Lieutenant-Colonel and Medical Director, National Guard of Missouri, 515 Olive Street, St. Louis; *Assistant Secretary*, Julian M. Cabell, Captain and Assistant Surgeon, U. S. Army, Washington Barracks, Washington, D. C.; *Treasurer*, Lawrence C. Carr, Major and Surgeon, National Guard of Ohio, 143 W. Seventh Street, Cincinnati; *Chairman Committee of Arrangements*, Albert H. Briggs, Major and Surgeon, National Guard of New York, 267 Hudson Street, Buffalo, N. Y.

The Buffalo Medical and Surgical Journal is fifty years old this month, and the editor, Dr. W. W. Potter, proposes to signalize its semi-centennial anniversary by enlarging the journal and making other improvements that will keep it abreast of medical progress. We extend our congratulations to our esteemed contemporary, and hope it will live to celebrate many more semi-centennials.

Cholera on the Red Sea.—The cholera is spreading rapidly in the quarantine lazaretto at Kemeran, on the Red Sea. There have been sixty deaths among the Mecca pilgrims landed by the steamers Mohammadi and Jubeda. The filth in the lazaretto is regarded as the main cause of the outbreak.

New York Lying-in Asylum, Blackwell's Island, N. Y.—Dr. Samuel Marx and Dr. Clifton Edgar have been appointed visiting obstetricians to the New York Lying-in Asylum, Blackwell's Island.

Infant Insurance.—A bill has been reported to the Massachusetts Legislature, providing that no life insurance company shall issue a policy upon the life of any child living in this State under ten years of age. The penalty is $100 for each offence, the law to take effect September 1, 1895.

Russian Precautions against Epidemic Disease.—Russia has established a medical staff at its consulate at Meshed in Persia, to watch and give notice of the appearance of epidemic diseases in Northern Persia. Caravans entering Russian territory must obtain bills of health from it.

The Austrian Health Resort, Toplitz, in the province of Carniola, has been almost entirely destroyed by fire. This is not Toplitz-Schönau, which is at the other extremity of the empire near the northern boundary of Bohemia.

Dr. John W. Coles, a retired surgeon of the United States Navy, died at his home in Philadelphia, Pa., on April 6th, aged fifty-five. He entered the navy in May, 1863, as an acting assistant surgeon. On January 14, 1867, he was promoted to passed assistant surgeon. His last service was as surgeon at the Philadelphia Naval Hospital and as a member of the Medical Examining Board. He was placed on the retired list on February 5, 1885.

The Cholera is very prevalent in various parts of China, including Hong Kong and the Portuguese possession of Macao, near Canton. The governor of Hong Kong has refused to declare a quarantine against Macao, despite the protests of many of the leading physicians of the city. The plague exists also in the northern part of the empire, and has been brought into Japan by the troops returning from China. In the Pascadoro Islands, where the Japanese forces have been stationed awaiting reinforcements, there were over eight hundred deaths from cholera up to the mid-

dle of April. The epidemic is said to be now abating. In the naval station of Moji, in Southern Japan, there were many cases during the early part of March, but the disease has since been stamped out. It is feared, however, that much disease will follow the return of the Japanese troops from China.

A Free Hospital is Not Liable.—In a case recently appealed to the Supreme Court of Connecticut where the plaintiff claimed damages for alleged maltreatment in the Waterbury Hospital, the Court sustained the plea of the defence that the hospital was not liable, as the treatment was made without charge and the attending physicians had no fees.

Charaka-Samhita.—The twelfth part of this interesting translation has been received. It deals with the effects upon the human body of various articles of diet, herbs, fruits, milk, wine and water.

A Medical Witness in Contempt of Court.—Dr. J. N. Dixon, of Springfield, Ill., was called as an expert witness by the city in a suit against the latter to recover damages for an injury sustained in a fall. The city refused to pay the witness anything for giving expert testimony, and the witness thereupon declined to give an opinion. The court held that he was obliged to answer the hypothetical question, whether paid as an expert or not, and upon refusal fined him $25 for contempt of court. Dr. Dixon has appealed to the appellate court of the State, and the question will be decided in May.

A Case of Leprosy was recently discovered in the Roosevelt Hospital in this city, and the newspapers are making as much noise over it as if it were one of cholera or the plague.

California Wishes its Quarantine Under National Control.—The California Legislature has before it a joint resolution providing "that our Senators in Congress be instructed and our Representatives requested to urge upon the Secretary of the Treasury that the Department assume entire control of the Maritime Quarantine Service at the port of San Francisco." Assembly Bill 627 is intended to separate the Quarantine Service of San Francisco completely from the present municipal authorities, and, in conformity with the joint resolution already referred to, place it under the exclusive control of the Federal Government.

An Anglo-American Medical Society, consisting of the English-speaking physicians of Berlin, has been organized in that city. The secretary is Dr. H. Wossidlo —which is not a Yankee name.

The Influence of Climate on Health and Disease is about to undergo a systematic investigation by the Department of Agriculture with a view to ascertain to what degree local climatic peculiarities may favor or resist the development of specific diseases, and to discover in what parts of the country invalids and health-seekers may find climatic surroundings best adapted to the alleviation or cure of their particular cases. The work is to be conducted through the medium of the Weather Bureau, and the co-operation of the various boards of health, public sanitary authorities, associations and societies, and of the medical profession generally, is earnestly solicited. What business the Department of Agriculture has with climatology, chemistry, bacteriology, and clinical medicine, we fail to see. Such work as this should be done by a National Bureau of Health, if the nation undertakes it at all.

Of the One Hundred and Forty Medical Schools in the United States there are, we believe, only fourteen which absolutely require a four-year course of medical lectures. Nearly one hundred schools announce that they graduate on three terms of lectures, and about twenty-five on two terms, the length of the term varying from five to nine months. The four-year colleges are—New York: College of Physicians and Surgeons, Medical College and Hospital for Women, Homœopathic Medical College and Hospital, Woman's Medical College of the New York Infirmary; Pennsylvania: University of Pennsylvania, Woman's Medical College of Philadelphia; Massachusetts: Harvard University Medical School, Boston University School of Medicine; Michigan: Department of Medicine and Surgery, University of Michigan, Homœopathic Medical College, University of Michigan; Illinois: Northwestern University Medical School; Tennessee: Maharry Medical Department of Central Tennessee College; Maryland: Johns Hopkins Medical School; North Carolina: Leonard Medical School.

Serum-therapy of Erysipelas and Puerperal Fever.—M. Roger claims to have discovered a new fact in relation to serum-therapy (*British Medical Journal*). He renders mules immune, and thus obtains a serum which cures erysipelas and puerperal fever. On February 6th a patient at the Maternity was treated with this serum for puerperal fever. Her general condition was very grave. Eight grammes of serum were injected without any result; the next day an injection of 16 gm. was followed by a slight improvement. On the third day, after an injection of 25 gm., the improvement was rapid; eight days afterwards the patient left the hospital. M. Roger's serum is efficacious in all maladies owing their origin to the presence of streptococci. Dr. Marmorek reports that he has used the serum in 46 cases of erysipelas with complete success.

A Monument to Villemin, the discoverer of the infectivity of tuberculosis, was unveiled in the military hospital of Val-de-Grâce, on March 31st.

Vote of the German Congress of Internal Medicine Upon the Diphtheria Antitoxin. — At the conclusion of the discussion before the above Congress on the value of the serum-therapy of diphtheria the following resolution was adopted: "That this meeting is of opinion that no harm had been done to the patients by the antitoxin treatment, that the majority of observers had seen good results, and that the experiments concerning immunization were not yet sufficient and should be continued."

Amalgamated Twins.—Dr. F. B. Heisordt (*Journal of the American Medical Association*) reports the birth of twins, the mother being a light-haired German woman and the father a negro; one of the twins was white and one black.

The Consumption of Absinthe has more than doubled in Paris in the last seven years (Lancereaux). The amount consumed in 1892 was 129,672 hectolitres.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 1, 1895.

BEVERLEY ROBINSON, M.D., CHAIRMAN PRO TEM.

Are There Seasons of the Year Favorable or Unfavorable for Surgical Operations?—DR. ROBERT ABBE read the paper. (See p. 516.)

DR. JOSEPH D. BRYANT said he had been very much pleased that Dr. Abbe had brought this subject to the fore. It was one to which we rarely found a line devoted in the text-books. Personally he had not given it much consideration, although he was aware of the fact that Richardson—he believed it was Richardson—had estimated from statistics that October, February, and May were the best months for operative procedures, while January and some other months which he did not recall had been stigmatized as being the most unfavorable.

Dr. Bryant thought it was a fair proposition that shock was more severe in cold weather and a dry atmosphere than in a damp atmosphere, by reason of the fact that evaporation from the body would be faster in the former case and perhaps militate slightly against recovery. He should feel that in a damp climate, or where the atmosphere was loaded with vapor, a patient suffering from shock would be comparatively safer than where the atmosphere was clear and dry. But he did not believe that this entered sufficiently into the case to warrant a surgeon in hesitating about a proposed operation. He should say that if it were possible to select a pleasant day for operating he would do it, not only on account of the effect upon the patient's sensibilities, irrespective of barometric influences, but also on account of light. On the other hand, he should never select a day when there was a rising barometer; he should prefer one when the barometer was falling or low. He did not wish, however, to have it assumed that he would hesitate for a moment with an operation with the idea that next week or next month the condition of the barometer or weather might have a better influence on the patient and the result of the operation.

DR. E. L. PARTRIDGE remembered that Dr. Emmet, in his book on uterine diseases, devoted about a page to the consideration of facts which he regarded as more or less adverse to successful major surgical operations where small things might turn the scale. He objected to a sunless day.

DR. W. T. BULL was in accord with Dr. Abbe in the view that writings upon this subject had apparently been based for the most part upon incorrect observation and explanation of facts. The question had been asked him frequently whether it was not undesirable to operate in the summer. His invariable answer had been that according to his experience patients did exceedingly well during the summer, and that many complications which flourished at other seasons of the year were entirely absent. He had based that statement on a pretty long experience with summer hospital work. The explanation was easy to find. In the summer the hospital wards were pretty thoroughly deluged with fresh air, and they were not as crowded with operative cases. The latter fact enabled the staff to give attention to every detail in the treatment. He thought the results of hospital work in the winter and spring months were not as good as in the summer for the further reason that the germs which caused suppuration and the inflammatory complications which attended wound healing were more active in hospital wards during winter and spring. Patients had frequently expressed to him the notion that they would not be as comfortable after an operation in the summer, and he had generally assured them that during hot weather people with a minimum of clothing lying abed were better off than those who were up and about their occupations.

Dr. Bull said he was aware that there was a notion among some physicians that erysipelas and other troubles might exist more at certain seasons of the year than at others. While he did not wish to name anybody in particular, lest he should misquote him, yet he was pretty sure that one of the surgeons of the Woman's Hospital had stated at one time that operations were less likely to succeed in February and March than at other times of the year. Dr. Bull thought the explanation was not to be found in the barometric or weather conditions, but rather in surroundings which favored at the one season suppuration and other accidents in wounds. He did not think the states of the weather outside had much influence on the heated air inside of hospitals where major operations were performed. He frequently observed a higher temperature in the rooms of hospitals in the winter than one had to deal with during the summer.

It might not be pertinent to the paper, but he would express the personal conviction that there was a disadvantage in accumulating a large number of patients who were to be operated upon in one institution. He thought the results were better in smaller hospitals than in larger ones. In order to give the members who were not surgeons an opportunity to participate in the discussion he would say that it seemed to him undesirable to have many patients with tubercular disease near surgical wards. It struck him that the accumulation of a large number of tubercular patients was likely to have far more influence on the course of surgical operations than the barometer or season of the year.

DR. GEORGE F. SHRADY had not had the pleasure of listening to the forepart of the paper, but taking the drift of the discussion which had followed, he ventured to add his testimony to that which had already been given with regard to the practicability of operating at any time and at any season and also at any place and under any conditions when it was considered necessary. He had operated in hospitals which had all the hygienic surroundings and in others in which these were deficient, and he did not recollect any particularly disastrous results even from formidable operations when the operations themselves were properly done, the patients ready, and the appliances at hand for observing antisepsis. He had done operations in the coldest weather, with the thermometer way down, and in the hottest weather in June, and he did not recollect any especially bad results from either of these extreme conditions.

In reference to barometric change, he did not think it had much influence. When the patient was ready, he thought the moral effect would be much better to operate at once than to wait for a fair day. He saw no other advantage in operating in the morning instead of in the afternoon than that one would have daylight in case of secondary hemorrhage or other accident a few hours later.

In reference to the presence of tuberculous patients in adjoining wards, he could not say that it had had any particular influence on the result of his operations at St. Francis', where a goodly number of tuberculous patients were on the same floor. In fact, although the beds were quite crowded there, they had exceptionally good results, and he attributed it to the fact that they carried out antiseptic precautions very thoroughly. In his opinion it was the treatment of the patient and of the wound, and the condition in which one placed his patient after the operation, which had more influence on the result than anything else, season of the year, time, place, barometric pressure, or thermometrical elevation.

DR. SAMUEL SEXTON said he had not had much experience in the hospitals of the city, and could not

speak of results from that standpoint. But he had always been impressed with the good results which they had had in the army during the war of the rebellion, where the wounded were treated in fields, in tents, during the summer, sometimes during the winter, during all sorts of weather. It was very rare to have any erysipelatous complications, and patients did well with all sorts of troubles which were surgically dealt with. He had often thought of that when reflecting on the overheating of hospitals in the city by indirect radiation from steam and hot-air pipes. He believed such overheating must be a great disadvantage in treating surgical cases.

One thing which Dr. Sexton thought had considerable influence on the effect of operations, was a feeble heart-action, which favored congestion and catarrhal inflammation, and it was his belief that the primary cause might be what one could call the electrical condition of the patient. Such tendency to congestion and catarrhal inflammation had been observed where the nerve-power was low, the heart-action feeble, and he had often thought such influences had been induced by conditions and surroundings of which little was yet known. It was well known to physicists that large collections of static electricity were floating about under the crust of the earth and that the terrestrial electrical conditions were changing constantly, and he had often thought that much of the depression observed after operations was due to withdrawal of electricity from the body. He did not know of any other way in which we got replenishments of electrical energy except from the earth. Probably we did not generate it ourselves, and yet it appeared to have an important influence on our being and on operations, although he was unable to make any exact statements with regard to it.

Dr. R. F. Weir remarked that the great trouble with material bearing on the subject under discussion which had been presented in the past was its unreliability. A statement of his preceptor was that if one could operate during the season of the year when the windows were open he would have better results. He had been interested in Dr. Bull's testimony, rather encouraging operations during the summer season. Dr. Weir himself had not operated much during the summer, but when he had he thought the post-operative course of the disease had not been quite so pleasant, yet it had not been seriously interfered with. He mentioned two works, one by Weir Mitchell, which had some bearing upon the subject.

Dr. Clement Cleveland had been interested in the subject in his connection with the Woman's Hospital, where it had been traditional a number of years that certain seasons were bad for operations. He remembered that during his early days at that institution as house surgeon, and for a few years afterward, February and a part of March were looked upon as the black months of the year. Dr. Emmet had postponed a good many of his serious cases in February until a later month. The speaker had compared the results of his own work during different seasons of the year carefully, and he had not found any difference. They no longer felt at the Woman's Hospital that there was any month of the year when it was unsafe to operate, and he thought the reason was the introduction of thorough asepsis and antisepsis. He did not know that anybody connected with the hospital now felt that February and March, for instance, were bad months.

Dr. A. A. Smith having been asked to make some remarks upon the influence of tuberculosis, replied that he thought there was more than a probability in Dr. Bull's statement regarding the influence of tuberculous patients upon surgical cases in the same hospital, However, he did not know that it could be proven. It was certain that tuberculosis was communicable, and communicable by way of open surfaces anywhere, under certain conditions.

The president, Dr. Robinson, made some remarks in connection with the statement, incidentally made in the paper, that in two cases of operations upon the nose, perhaps necessary ones, pneumonia or respiratory trouble followed. It might not be in direct line with the discussion, but Dr. Robinson wished to express his firm belief that a great deal of unnecessary surgery was being done upon the nose, especially in view of the ultimate result upon the respiratory powers of the patient. Only last evening the statement had been made in his presence at a musicale that one of the singers had this winter submitted to a surgical operation upon the nose, since which time she had had a series of colds which she had not been able to check. It was perfectly clear in Dr. Robinson's mind that an unnecessary operation upon the nose would be likely to result in an extremely sensitive condition of the respiratory organs, a degree of sensitiveness which it would take long to get rid of. The nose was an organ which had numerous functions, and certainly one of those functions was to regulate in a large degree the temperature of the inspired air. If then, one made, for instance, an unnecessary hole through the nose, he felt certain that it would produce serious effects, although nothing might be immediately obvious except much discomfort to the patient.

Dr. Abbe made some concluding remarks. He had been glad to hear the remarks of the gentlemen who were in a position to speak with authority. In general they had corroborated his own experience. He admitted to having long had a sort of feeling that there were certain seasons of the year when it was unfavorable to operate, but on looking up the statistics of operative work he had satisfied himself that there was no ground for the feeling. He did believe, however, that there was a very strong personal equation which probably affected every surgeon, and was, perhaps, the cause of a prejudice in his mind against certain seasons. For instance, in the spring of the year we were apt to be tired from the protracted work of the winter and to feel much depressed when for any reason cases went unfavorably, and we were disposed to attribute it to the season. But when gynecologists, for instance, were able to report a series of one hundred successive laparotomies without a death, it was pretty good evidence of the safety of operating at all seasons of the year. Regarding the notion that the summer diarrhœa of children carried off so many patients after surgical operations, he would admit that it might complicate the case, but he did not think the possibility of such occurrence ought to interfere with surgical work.

Respecting the barometric pressure, that was a different thing, it varied from week to week and from day to day throughout the year. He had never seen but one instance, and this was a striking one, where a falling barometer seemed to have had a decided influence on the patient's condition. Several years ago he attended a child of three years very low with erysipelas. Yet he saw no reason why it should not recover after one or two days more of fever. There came up a very violent thunder-storm and depressing condition of the atmosphere, which even influenced himself. He was in another part of the city, yet feeling it might not be well with the child, he hastened to its bed-side and there learned that he had been sent for; the child seemed moribund. Undoubtedly it had been depressed to the lowest degree by the devitalizing influence of a rapidly falling barometer. During the peals of thunder and strokes of lightning he worked over the child an hour or two, and with difficulty succeeded in restoring it to life. He had since then felt anxiety for very ill patients during rapid change of barometric pressure, and he thought there was some reason for it, but that was only incidental to the subject of the influence of the seasons.

Regarding tuberculosis, Dr. Abbe said he did not think it had anything to do with general hospital crowding.

Case of Landry's Paralysis.—Dr. Beverly Robinson reported the following case:

John W——, aged nineteen ; German ; single. Family history negative. Personal history : Rheumatism five years ago, was laid up nine months with it. Denies cardiac, hepatic, renal, or venereal history. Patient has only a moderate alcoholic habit. Present trouble began last Friday with numbness in feet. This lasted till Sunday, when patient lost power in legs and arms ; at this time there appeared pain in lumbar region and in limbs.

October 3, 1894.—To-day dysphagia has appeared and he has vomited. Patient was exposed to cold and wet while out fishing a week before onset. Patient well nourished, face flushed. Heart apex fifth space in nipple line ; impulse slightly heaving ; action regular ; no murmurs. Lungs, liver, spleen, and abdomen negative. Knee reflexes abolished. Marked loss of power in lower extremities, more particularly in flexion. There is tenderness on grasping legs and thighs and apparently some diminution of sensitiveness. Marked loss of power in grasping, especially in right arm, also diminution of power in moving arms, more marked on right side. Sensation of conjunctivæ greatly diminished. Pharynx markedly anæsthetic. Renal muscles seem somewhat inactive. Tongue slightly coated. Patient unable to protrude tongue to full extent or to open mouth widely, also dysphagia. Pulse regular, soft, good force.

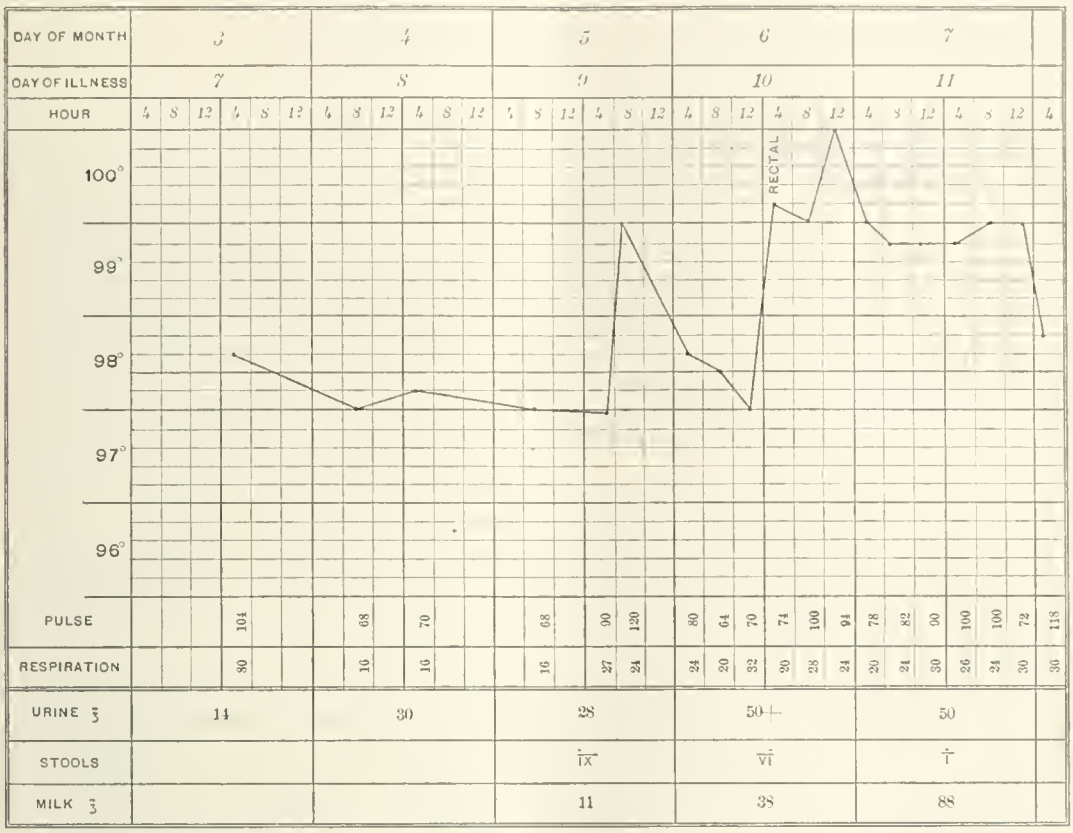
October 4th.—Patient troubled with pain in back ; unable to take solid food ; fluids taken with difficulty. Dry cups to spine. Gave fluid extract of ergot, one-half drachm, four times a day. Urine, specific gravity, 1034 ; acid ; albumin, a trace ; no sugar ; microscopic examination negative.

October 5th.—Pain in back and legs. Patient vomits. Has considerable dyspnœa. Allow milk diet. Dysphagia marked. Stop ergot. Gave sulphate of strychnine, one sixtieth grain, every four hours. Eyes examined by Dr. Bull. Simple hyperæmia of retina.

October 6th.—Headache and vomiting. Unable to swallow fluids. ℞. Nutritive enema oz. vj. every four hours. Severe attack of dyspnœa, patient becoming cyanosed. Involuntary movement of bowels. Stop enemata. Patient fed from this time by stomach-tube. Pulse good force and regular all day, but late this afternoon began to be slightly irregular.

October 7th. — Condition apparently the same. Rested quietly all day. Complained of pain when moved in bed, also some pain when muscles were grasped. Bowels moved once voluntarily, also passed urine voluntarily. Respiration has been very shallow all day. During the evening the pulse began to intermit, respiration became more shallow and irregular.

October 8th.—Respiration and pulse both failed rapidly in spite of stimulation and patient died about 6 A.M., apparently rather a cardiac than a respiratory death.



Autopsy. — Frame large ; muscle good ; adipose moderate. Diaphragm : Right side, fourth space ; left side, fifth rib. Heart : Normal ; weight, 12 ounces. Lungs : Left, posterior portion congested, muco-pus in bronchi, weight 1 pound 5 ounces ; right, same. Liver, congested. Spleen, normal. Kidney : Left ureter and adrenal normal—8 ounces ; capsule slightly adherent ; surface smooth ; congested on section ; cortex congested ; right kidney, 7½ ounces ; left kidney the same. Pancreas, normal. Bladder and prostate, normal. Brain, some congestion. Spinal cord, blood-vessels appear rather congested ; no softening. The dura mater is normal ; the pia mater is congested. The convolutions of the cerebral hemispheres are flattened, most markedly over the right parietal lobe, where there is some bulging, and where the tissues are softened to the touch. There is also some bulging of the central portion of the mesial surface of the right hemisphere.

On section of the right parietal lobe, there is found a tumor mass, 2½ inches in diameter, extending from one-half inch beneath the upper surface down into the corpus callosum, and involving to a slight extent the left half of this body and the right fornix. It also crosses to the floor of the right lateral ventricle, and involves the tail of the caudate nucleus and the superficial part of the internal nucleus. It extends forward to the fissure of Rolando, and backward to within one inch of the parieto-occipital fissure. It is mostly of a pinkish color, but some parts are brown, and some are dark red. In consistence, the posterior central portion is much firmer than normal brain-tissue, but most of the peripheral portions are soft, and in parts there is a striking richness in serum.

On microscopical examination of stained sections the tumor is found to be a spindle-cell sarcoma. There is also much hemorrhage, and there are necrotic patches.

Sections have been made from some twenty portions of the spinal cord, also the cauda equina at various levels, and from several nerve-trunks. Most of these sections have been stained by three different methods — Weigert's hæmatoxylin, Delafield's hæmatoxylin, and Van Gieson's picro-fuchsin; and they have been carefully examined under the microscope. No lesion, inflammatory, degenerative, or of any other nature, has been detected. The nerve terminations in the muscles were not examined.

Dr. C. L. Dana thought the case read like a typical one of Landry's paralysis, and the only criticism which could be made, related to what appeared to be an incomplete post-mortem examination. In such cases a bacteriological examination of the nervous system seemed to him of first importance, the autopsical record being quite incomplete without it. Furthermore, the microscopical examination of the nervous tissue was quite incomplete unless the tissues had been hardened in alcohol without any touch of bichromate solution, and had been submitted to methyl-blue stain, etc., by which we were able to detect changes in the nerve-cells which could not be done by the methods mentioned, as he remembered them in the record of the case.

Dr. Robinson regretted that Dr. Thacher was not present to reply to the criticisms made.

Dr. Dana added that it might seem ungrateful to make criticisms in the absence of Dr. Thacher, but he wished to impress the fact that this disease was one the cause of which could not be discovered, it seemed, by the methods of examination applied ordinarily; that it was probably a disease of infectious origin in which the nervous system was overwhelmed by the poison, like in some cases of paralytic rabies.

Dr. Robinson remarked that ergot was given because it had been used in the form of ergotine in one case by Gowers.

Case of Brain Tumor.—Dr. Robinson presented a specimen with the following history:

W. H. De G——, aged thirty-one; male; clerk, New York. Family history: One brother died of phthisis. Personal history: Patient suffered from an attack of scarlatina when a child. Thirteen years ago had trouble with both ears. Moderate alcoholic habit. Denies venereal. Otherwise negative.

Present trouble began three months ago, when he noticed that his left leg was weak, and foot showed a tendency to turn in and interfere with the other leg in walking. This has gradually increased, and now he does not have full control of leg or of fingers on his left side. He had headaches which are very severe, and perhaps most severe through the temples, but the site of the pain is not at all constant; pain in back of neck is also very severe. The headaches, when especially severe, at times cause nausea. Has had vomiting nearly every day since first onset of paralysis and headaches. Vomiting is projectile, and often relieves the headache. He has also suffered from dizziness, associated with dimming of sight and pain in eyeballs. All of these symptoms have gradually increased in severity up to time of admission. Bowels are constipated. Appetite poor. Chief complaint, pain in the head. On admission physical examination showed the patient to be well nourished; color good; heart, lungs, liver, spleen, abdomen, and superficial glands apparently normal; tongue slightly coated; pulse regular, soft, fair, force about 90; knee-jerk markedly exaggerated on left side, slightly so on right side; plantar and cremasteric reflexes present; ankle clonus on left side; sensation apparently normal; left leg cooler to touch than right; elbow and wrist reflexes present, more marked on left side; fine movements of fingers good. Power in both arms good. Flattening of right side of face, slight ptosis of left eyelid. Urine, specific gravity, 1029; no albumin; no sugar; microscopic examination negative.

Examination of eyes a short time after admission showed that right eye had suffered from a mild degree of neuro-retinitis. Left eye negative. In consensual movements of upper lids, right acts slightly; left acts better. On walking toes of left foot drop; gait is slightly spastic; swings left leg from hip and staggers a little to the left. Weight, 148 pounds. During first week patient was able to get up each day and walk around a little; had almost constant headache. Vomited occasionally.

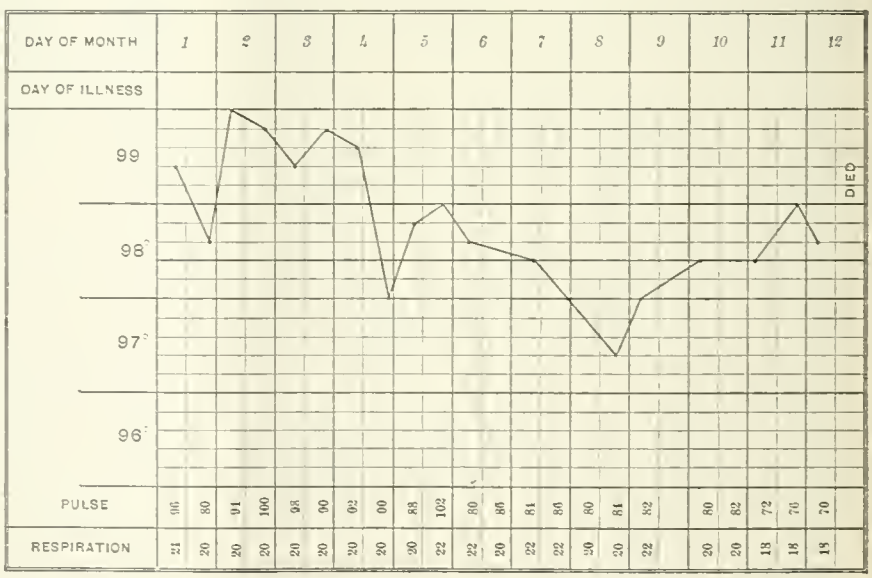
January 23d.—Put on inunctions of hydrarg. and potas. iodid. internally. Weight, 141 pounds. During a dizzy spell fell out of chair to-day. Delirious during the night.

January 25th.—Right side of face decidedly flatter; power in left arm and leg is much diminished; movements of fingers on left hand are very imperfect and feeble. Pulse slow and irregular. Slightly diminished sensation over left side of body.

January 27th.—Pain in head; vomiting and delirium continue. Power in left arm and leg is almost nil. Slight nystagmus noted. Sensation over whole left side of face, trunk, and extremities is still further diminished.

January 28th.—Eyes examined. Neuro-retinitis in right eye has increased. Left eye has a few spots of retinal exudation. Wildly delirious at times, stupid and drowsy at others. Urine and fæces are now passed involuntarily. Headache and vomiting continue.

February 1st.—Still getting iodide and inunctions. Headache is constant. At times is quite bright, at others delirious or in a stupor.



February 4th.—Growing weaker and more stupid. Stopped iodide and mercury.

February 6th.—Paralysis of right side of face seems less marked. Patient has difficulty in swallowing.

February 7th.—Comatose all day.

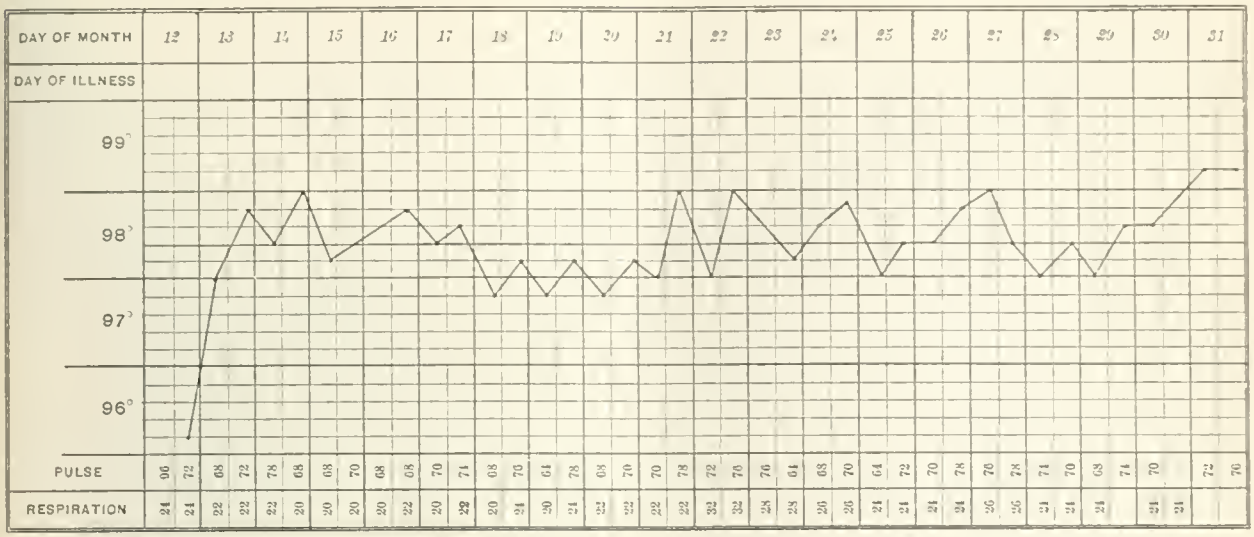
February 10th.—Anæsthesia seems less marked than formerly. Mental condition is better. Slight movements of left fingers possible; otherwise left extremities are completely paralyzed.

February 11th.—Ptosis in left eye more marked.

Paralysis of left side of face now, while right side seems to have recovered.

February 12th.—Stupor all day. Right pupil larger. Respiration labored; pulse irregular.

February 13th.—Died.



Autopsy.—Brain: Dura normal; pia congested. Convolutions of cerebral hemispheres flattened most markedly over right frontal lobe, where there is a slight bulging and where tissues are slightly softened to the touch. Also some bulging of mesial part of right hemisphere. On section of right parietal lobe there is found a tumor mass 2½ inches in diameter, extending ½ inch from convex surface down into corpus callosum, and from fissure of Rolando in front to within one inch of parieto-occipito fissure behind. It is mostly of a pinkish color. Some parts are brownish and some parts dark red. Central portion firmer than brain tissue. Most of peripheral parts are soft and in places rich in serum. Central portion of corpus callosum and of right fornix are invaded. Rest of organs about normal.

Tumor of the Cerebellum.—Dr. Charles L. Dana, in presenting a specimen of cerebellar tumor, said he was indebted for it to the scientific zeal of his house physician, Dr. Russell, who had followed the case after the patient left the hospital and obtained an autopsy. The patient was a man forty-two years of age, with a good family history and a good personal history up to about a year and a half ago, when the present symptoms came on. The first symptom which he noticed was pain in the occiput. After this had continued for some weeks, there came on some disturbance of gait, stumbling, and awkwardness. These were the two principal symptoms for a year. He entered Dr. Dana's service in Bellevue in November, 1894. He was then able to walk with difficulty; the gait was slow, straddling, and somewhat titubating, and there was a slight tendency to fall toward the right. The legs were weak, both knee reflexes were exaggerated. There was no spasmodic trouble. The arms were free from any trouble whatever. No paralysis of the facial muscles, no anæsthesia. The only sensory symptoms from which he suffered were intense pains in the head, especially in the occiput. There was neuritis in both eyes. He swallowed with difficulty, soon began to vomit some, the speech was not very perfect. On the ground of persistent occipital pain, peculiarities of gait, vomiting, optic neuritis, vertigo, and forced movement, Dr. Dana made a diagnosis of tumor of the cerebellum. The patient suffered so much from pain that he had him transferred to the surgical ward, and suggested that at least an exploratory operation be made over the cerebellum, taking out a piece of bone to see if it would relieve pain, and at the same time feeling for a tumor and possibly removing it. But the patient improved so much in the surgical ward that the surgeons decided not to operate, and he was returned to Dr. Dana's service, where he continued to improve, and finally was able to walk about a little and left the hospital. He had simply been taking iodide of potash Dr. Russell followed him up, the symptoms recurred, no new ones developed, there was great nausea, vomiting, prostration, and difficulty in swallowing, and finally death.

The autopsy revealed a tumor an inch and a half in diameter, of rounded form, almost entirely encapsulated, attached to the anterior portion of the right lobe of the cerebellum, pressing upon the right lateral surface of the medulla and to some extent upon the pons; also pressing upon the right cerebellar lobe to which it was attached, somewhat upon the median lobe, but there could not have been much pressure directly upon the medullary centres or cranial nerves in front of the medulla. Microscopical examination showed that it was a spindle-cell sarcoma.

Dr. Dana said the case was especially interesting to him as he believed it was one in which the cerebellar tumor could have been successfully removed. Examination of the specimen might give the surgeons a little encouragement in attacking these cases.

Dr. Abbe inquired whether the tumor had very vascular attachments.

Dr. Russell replied that it was a pretty vascular tumor, but it had no large vascular attachments.

Dr. Polk inquired what had been the mortality from operations for cerebellar tumors.

Dr. Dana, one hundred per cent., I presume.

Dr. Bryant believed Starr's figures were, of eighteen operated upon, one recovered.

Jewish Physicians to the Popes.—According to a writer in the *Rivista de Ciencias Médicas*, the records contained in the archives of the Vatican show that many of the Popes employed Jewish physicians, and in return for their services protected them in the exercise of their ancestral religion. Angelo de Manuele, a Jew, was appointed physician to Boniface IX. and the conclave of cardinals, in 1392. Julius II. had for his doctor a Spanish rabbi. The Popes of the Renaissance, Leo X., Clement VII., Paul III., all employed Jews.

The Passing of Red Hair.—A writer in *The Lancet* says that he has noticed, during several years' experience in civil service examinations, that a diminishing number of the candidates have red hair, and he thinks this color of hair is becoming quite rare.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL SURGERY.

Stated Meeting, April 8, 1895.

B. FARQUHAR CURTIS, M.D., CHAIRMAN.

Plastic Operation on the Nose after Excision for Sarcoma.—The Chairman, DR. CURTIS, presented an aged man, on whom he had operated for what appeared clinically like epithelioma of the face and nose, but microscopical examination pointed to sarcoma. The tumor was the size of a quarter of a dollar, flat, elevated slightly above the surrounding surface, and during its removal it was necessary to take away the entire ala of the nose on that side. A flap was cut from the cheek, somewhat larger than the gap in the nose, leaving a pedicle attached at the corner of the ala, was sutured in position, and uniting it formed a very fair-looking nose. The great difficulty in making a new ala to the nose ordinarily was the tendency for the flap to lie flat against the septum, but in this case it had stood out sufficiently to allow a little for shrinkage. The operation had been done less than two weeks ago and healing was practically complete.

The Operative Treatment of Bending of the Neck of the Femur.—The Secretary, DR. ROYAL WHITMAN, presented the youth whom he had shown at a former meeting with bending downward of the neck of both femora and also a twisting backward, so that the greatest amount of separation of the legs obtainable was three inches and a half. In sitting he had been compelled to cross the legs. Dr. Whitman presented the patient a second time, in illustration of the result of osteotomy for the correction of the deformity. The bone was placed in a position at the completion of the operation corresponding to the normal position of the foot. The idea at first was to correct the deformity of both limbs, but it was decided to first see what would be the result on one side. It had been highly satisfactory, the foot now being in normal position, flexion normal, gait easy. Dr. Whitman said the method was far superior to that commonly resorted to on the continent, excision of the hip. He mentioned the fact that cases of bending of the neck of the femur were almost invariably mistaken for hip disease.

Fibro-Cystic Tumor of the Cord (?) Complicating Inguinal Hernia.—DR. W. B. COLEY, presented a youth, aged eighteen, on whom he had operated for supposed irreducible, inflamed, inguinal hernia. There was a small tumor between the testis and external ring. This tumor was found to have thick walls of fibrous nature with small cystic cavity. He could not say whether it was attached more to the cord or to the lower end of the hernial sac. There was no sign of malignancy. The case also illustrated how little the testis was affected by an operation involving transplanting the cord.

Cases of Sarcoma Cured by Toxins of Erysipelas and Bacillus Prodigiosus.—Dr. Coley also presented again three patients, cured of sarcoma by inoculation with the toxins of erysipelas and bacillus prodigiosus, whom he had shown at other societies and whose histories had been published in the MEDICAL RECORD. One was a man who had had inoperable sarcoma of the back and groin, another a younger man with inoperable sarcoma of the abdomen, the third a woman who had had inoperable sarcoma of the back and shoulder. In none had there been any sign of recurrence, and the health had been perfect.

The Treatment of "Saddle Nose" with Celluloid Support.—DR. R. F. WEIR presented a woman and photographs, showing the result of the treatment of "saddle nose," a subject which had occupied the attention of surgeons interested in deformities a long time. He had once thought of making it somewhat a specialty. The first material which he had used for a support was gutta percha, but it proved unsatisfactory because it softened underneath the skin and was not always tolerated. Having been experimenting with covering holes in the skull with celluloid, an idea which he had gotten from the Germans, and finding the material borne well there, he had then tried it as a support for the nose. The result had been quite satisfactory. The boat-shaped piece of celluloid was best introduced through an incision into the skin at the side of the nose. Only a very slight scar was left. He had tried introducing it from within the nostril, but twice he had been compelled to remove it, finding that there was not sufficient bed beneath it and trouble arose from gravity pressure. Photographs were shown of another case in which, through an incision in the cartilage within the nose, bone was chiselled out and the contour of the nose restored. But a case which illustrated better than any other what liberties could be taken with this organ, was that of a man of exaggerated oriental features relating to both nose and lips, which were very prominent. Through an incision in the nostril he chiselled away part of the bone, removed a V-shaped section of the cartilage, later made a V-shaped incision inside of the mouth and brought down the lip. The man's expression was changed very much, so that his friends were greatly astonished. He told them that he had been out riding one day, had fallen from his horse, and this was the result.

The Result of Operation for Anchylosis of the Elbow.—Dr. Weir next presented a lad who had some weeks before he saw him sustained complete outward dislocation at the elbow, resulting in anchylosis at an angle of 160°. The main obstacle to reduction of the dislocation was found in a strip of periosteum turned up from the coronoid process which had undergone such thickening and hardening as to cause the parts to be extremely rigid ; also in a similar piece of periosteum on the anterior surface of the humerus. With some little difficulty these were cut away, the joint was put in proper relation, and there had been a very satisfactory result from a troublesome case.

Compound Comminuted Fracture of the Patella.—DR. E. M. COX presented a boy who had been brought to Roosevelt Hospital soon after falling to the ground from a height of four stories. There was fracture of the right femur and of both bones of the other leg, but the point of chief interest related to the right patella, which had sustained a compound comminuted fracture, the number of fragments being at least seven or eight, some of them very small. He opened the joint, cleansed it of clots, stopped bleeding, removed the smallest fragments of the patella, drilled the larger ones and united them with catgut, and also united with them the small portion of bone to which the ligamentum patella was attached. The only interruption with healing was necrosis of a small fragment, which finally came away and the sinus closed. The result has been perfect function.

Foreign Body in the Knee-joint.—DR. WEIR presented a man on whom he had operated for foreign body, cartilaginous in character, in the right knee-joint, to the right of the patella, where it was adherent, but free enough to make moderate excursion and cause trouble. It was tied and cut away, but in closing the wound he adopted a method which he would not recommend, namely, first sewing up the serous membrane, then the fibrous tissue, then the skin, not leaving an opening for drainage. In this case the result had been entirely satisfactory, but in a later one the method had caused trouble, and he would advise in its stead the old plan of leaving an opening for the escape of any effusion.

Undescended Testis.—DR. JOHN B. WALKER read a paper on this subject. The testes appeared at the internal ring about the seventh month of intra-uterine life, and reached the normal position about the eighth month, the left testicle preceding the right from three to four weeks. But in a considerable number of cases the nor-

mal descent of the organ did not occur. This might be due to one of several causes—to adhesions formed during fœtal life, to lack of function of the gubernaculum, to contraction of the ring, later to pressure of a misapplied truss.

Harm Resulting from Retention.—It had been shown in animals that the testis must descend in order to perform its function of secreting spermatozoa. A man or animal in whom both testes were retained was impotent. The testis might be retained within the abdomen, in the canal, or just outside, but the most common place was in the canal. Photographs of cases were shown. The descended testicle, usually the left one, was, as a rule, four or five times larger than the retained one. The pressure on the testis retained in the canal was apt to cause it to undergo degeneration and to take on sarcomatous change. The organ was especially susceptible to inflammatory process, and there had been numerous cases of orchitis under such conditions. The best theory was, not that the organ was from the beginning imperfectly formed or developed, but that it had not reached full development, and that if it were brought down before the age of puberty it would develop into a normal testicle. After the first year it rarely came down unless operated upon or was carried down by a hernia. In infants we found undescended testis without hernia, but in adults there was usually hernia. Out of 65 cases of undescended testis in his list 55 were attended by hernia.

How to bring the Testis Down.—The simplest method to bring the undescended testis down was by manipulation, but this was not sufficient for a cure, and had to be followed by an operation. The manipulation should be begun early in infancy. An operation should not be done before the age of five, but it should be done before puberty, say at eight or ten years of age. The essential part was to free the bands. All tissues should be divided except the vas. In some cases where it seemed too short the epididymis could be dissected away from the testis so that the testis could be inverted and allowed to go down an inch or two farther. To prevent the testis from rising, some operators had fastened it by suture to the scrotum, and to prevent the scrotum from becoming invaginated had fastened it by suture to the skin of the thigh, or a wire mattress.

In illustration of the benefit of operation, Dr. Walker had collected about sixty-six cases operated upon before the age of puberty, in sixty of which the testis had gone on to grow to about the normal size.

The Chairman, Dr. Curtis, said he had operated on a case of hernia and undescended testis ten days ago. By closing the canal after the Basini method it did not seem so necessary to sew the testis to the scrotum. Of course one could not get much support from the scrotum. He thought the Basini method would help very much in dealing with cases of undescended testis with hernia.

Twisting of the Cord.—Dr. Lilienthal mentioned an accident to which Dr. Vanderpoel had recently called attention, namely, twisting of the cord, which was more likely to take place where the cord was short, as it was where the testis was retained.

Dr. W. B. De Garmo mentioned the fact that stallions during violent exercise carried the testes in the abdomen. Undescended testis was sometimes mistaken for hernia, and he recalled an instance where a fitter of trusses had set up in a man an orchitis when there was no hernia, but retention in the canal of both testes, which were of good size. He had seen some very satisfactory results from the use of a truss alone, while in others the testis had made scarcely any downward progress at the end of ten or fifteen years. Still, he had the persons continue the use of the truss because he believed the canal was weak in these cases and hernia was likely to occur. He had seen descent take place at almost every age up to the fifty-ninth year. One man, aged fifty-nine, had carried one testis in the abdomen all this time and then it descended. He had seen some cases in which manipulation had been useful. He believed the author had not stated whether he opened the inguinal canal. It was necessary, in order to bring the testis into normal position. These people were frequently subject to violent pains, due apparently to contraction of involuntary muscular fibres pressing the testis against the ring. A truss had given relief, he hardly knew why.

Dr. De Garmo said that Mr. Fenwick had operated for hernia in a man with undescended right testicle, leaving the testicle; the left testicle was atrophied. The man had been married but had no children. Shortly after the operation he married again and a child was born.

Opposed to Operation.—Dr. W. B. Coley had about two years and a half ago operated upon three cases of undescended testis, anchoring the organ in the scrotum in two by wire frame, in one stripping off epididymis in order to gain a little in distance. The patients had been kept under observation and he could say that in all there had been greater atrophy than would have taken place had the testis been left in the canal. He did not think the testis was improved upon at all by bringing it down and anchoring it in the scrotum. In the vast majority of cases, in children, at least, operation was not at all necessary. In adults, where there was much larger hernia, acting as a serious complication, he thought an operation should be performed. It was very seldom necessary in such cases to remove the testis, as had frequently been done. A good surgeon had told him that he had recently operated for hernia, found a testis, removed it, tied it carefully with three ligatures, yet hemorrhage occurred and the patient died of hemorrhage, shock, and peritonitis. There was, then, some danger in removing the testis. He had seen a man who had sustained injury of one testis, which was accordingly removed; the other was undescended, yet he became the father of three children.

Dr. T. H. Manley said that gynecologists did not hesitate to remove the ovaries, not only when they were diseased, but even when disease was only suspected. In undescended testicle in man, the organ was not even developed; it was a foreign body, why not remove it? Some of the worst cases of strangulated hernia which he had seen had been complicated by undescended, undeveloped testicle, and under such circumstances he had removed the organ. He could not understand why there should be danger of hemorrhage.

Dr. De Garmo thought also that in operating for hernia and a small testicle was found which could not be brought well outside of the external ring, it ought to be removed. It was true death had resulted from removing the testis, but the fault must have rested with the operation. To retain such a testicle was purely a matter of sentiment.

Dr. Walker said he had stated that all the tissues should be divided except the vas. A case had been reported in which the cremaster had not been divided; the testicle was drawn up against the pubic bone, causing great pain, and relief followed subsequent division of the cremaster. It had been observed that where the operation was done before puberty, in bringing the testicle into normal position, it went on to develop.

Demonstration of a Method of Preparing Catgut.—Dr. R. H. Cunningham made the demonstration. In some experiments he had determined to try hardening catgut in formalin, an agent which had been shown to possess great potency as a germicide. For the hands it had to be employed in very weak solution, else a peculiar necrosis of the skin would occur, a necrosis not accompanied by signs of inflammation. Formalin was capable of uniting with gelatin in forming a film. Take commercial catgut, wound not too tightly on a glass spool, soak it two days in a mixture of absolute alcohol and ether, equal parts, and thoroughly remove the grease. Then immerse in alcohol a few moments. Then remove to a jar with a tight cover, in which

there were equal parts of formalin, alcohol, and boiled distilled water, sufficient to submerge the catgut. After two days (a few hours would probably do) the catgut could be removed, the formalin washed out, the catgut soaked several times in fresh alcohol, or, what he preferred, boiled in normal saline solution half an hour or more. Then it was transferred to alcohol for preservation until used.

Catgut so treated was found to have undergone a peculiar change, so that it did not become stiff and brittle, and even on boiling in water several hours it did not lose its strength. The fact that it could be boiled without destroying it was very important for a number of reasons: 1. It facilitated the complete removal of the irritating formalin. 2. A more aseptic state was produced. 3. It could be again boiled in saline solution just before using it, thus avoiding bringing alcohol, oil of juniper, or other preservatives, in contact with the delicate tissues. Other animal substances, such as decalcified bone, could be thus prepared also. Dr. Cunningham had had experience with catgut thus treated only in experiments on animals, and the results had been quite satisfactory, even on the sensitive brain.

The Chairman and others present thought this method of preparing catgut would prove of the greatest value.

Final Result of Intestinal Anastomosis by Suture.—Dr. P. R. Bolton presented a specimen removed at autopsy from the case of the man related by Dr. Weir some months ago. Dr. Weir had made intestinal anastomosis by suture between the ileum and sigmoid flexure, establishing an opening 7.5 ctm. in length. There had been no contraction. Silk sutures were used, but all had disappeared.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE ROYAL COMMISSION ON THE AGED POOR—PARASITES OF MALIGNANT DISEASE—PRESIDENCY OF THE COLLEGE OF SURGEONS—THE PUBLIC HEALTH—INFLUENZA—DIPHTHERIA.

London, April 5, 1895.

The Report of the Royal Commission on the Aged Poor has been looked for with no little interest by various sections of society, and to medical men the questions involved are always present—like the poor themselves. The expectations formed are largely doomed to disappointment. Of course there are not a few who foresaw that such an inquiry could result in no definite conclusions, and some who had not so much perspicacity are assuming the airs of those who had. If no definite conclusion on which legislation can be based is offered, the commission has certainly stimulated public interest in the great social problem involved. We have now the report of the majority, but with it another, that of the minority, of the commissioners. Even to the former, which we may regard perhaps as the official statement, several of the signatories set forth in addenda the points on which they differ from their co-signatories. Such divergence of view illustrates the extreme difficulty of the problems involved, and should tend to raise serious discussion with a view to definite results, and independent of all political party. It is a sad state of society that three out of seven of the industrial classes who reach the age of sixty-five should be driven to depend on the Poor Law. This glaring fact has given rise to various schemes of insurance and State aid. The majority of the commission say no such scheme is free from grave dangers, while the minority declare that this is only destructive criticism, and that a constructive policy should have been attempted.

On Tuesday last Mr. Jackson Clarke returned to the question of protozoa anent a lobulated growth of the breast, the histology of which he carefully described. He slightly modified his former conclusions, which I have fully reported, in consequence of appearances that pointed to the bodies he described as perhaps suctoria rather than protozoa, but this he left for biologists to decide. He also said the parasites of vaccinia and variola were identical with some of the phases seen in the present sarcoma, and he referred to the question of molluscum parasites. Mr. Shattock and Dr. Kanthack both joined issue with Mr. Clarke. The former proposed that the specimens should be submitted to the Morbid Growths Committee to test the accuracy of the facts and observations recorded. The latter considered the appearances presented were those of degeneration products. Mr. Clarke replied that he would submit his specimens to the Morbid Growths Committee on condition that they publish the photographs he supplied with their report. He was not satisfied with the treatment of his specimens on former occasions by that committee.

In consequence of the death of Mr. Hulke, Mr. Christopher Heath has been chosen by the Council of the Royal College of Surgeons to be president for the remainder of the collegiate year which closes on July 11th. Mr. Heath is a strong man, and expresses his views with force. If he lacks any qualification for such an office it is the degree of *savoir faire* which never irritates opponents. He has several times spoken out about abuses in a manner which shows the honor of the college will be safe in his hands.

Influenza is still declining, though there were 116 deaths from it last week. Still that figure is a decline on the prior week of more than 100. So also the deaths referred to diseases of the respiratory organs have again fallen, but are still 48 above the corrected average. The fall is, however, marked from 740 to 497. The epidemic is also on the wane in the provinces, but in some towns the death-rate continues abnormally high—in one town 42.4 per 1,000. Although in practice one now sees comparatively few fresh cases, there is a heavy crop of sequelæ.

The mortality from diphtheria has again risen. The deaths, which had declined to 24 the previous week, rose again last week to 31, which is 6 above our corrected average. All the 31 were under twenty years old. The numbers, however, are less this year than last, and this epidemic is generally considered milder than the preceding one. If we take the returns of the last three months we find the mortality 1,740, which is between 800 and 900 less than during the same period last year.

DISCUSSION ON NERVOUS SYMPTOMS AND CHANGES IN THE CORD IN CASES OF ANÆMIA.

(From our Special Correspondent.)

London, April 5, 1895.

At the last meeting of the Royal Medical and Chirurgical Society Dr. James Taylor read a paper on "Nervous Symptoms and Morbid Changes in the Spinal Cord in Certain Cases of Profound Anæmia." Lichtheim's observations in 1887, and those of his pupil Minnich, were referred to, and showed that in certain cases of pernicious anæmia symptoms of sclerosis in different areas of the cord were present. The actual degeneration found in the cord, chiefly marked in the posterior columns, was described, and also the conditions found in the cord of patients the subjects of pernicious anæmia, but in whom during life no symptoms of cord disease were present. Subsequent observations by Van Noorden, Eisenlohr, Nonne, Bowman, Putnam, Grainger Stewart, and Bullock were mentioned and then Dr. Taylor described two cases observed by himself. The first was that of a woman, aged fifty, admitted to hospital with symptoms of ataxy and in a

condition of considerable anæmia. She gradually became weaker, developed excessive spasticity of the limbs, lost control of the sphincters and died of exhaustion. The cord showed marked degeneration in all areas of the white matter and little or no change in the gray. The second case was that of a man, aged forty-three, admitted with symptoms closely simulating those of locomotor ataxy. He became gradually weaker, retinal and subcutaneous hemorrhages were present, and he died from exhaustion. Similar extensive degeneration was found in the white matter of the cord, the cells in the gray matter being unaltered. Dr. Taylor regarded the association of extreme anæmia and spinal-cord changes as no mere accidental one. The cord changes he regarded as of double origin: 1, sclerosis resulting from small hemorrhages similar to those occurring in the retina in the same disease; and 2, sclerosis is the result of a blood state, and he instanced as analogous the posterior sclerosis found by Williamson in cases of diabetes, and the sclerosis present in the cord in cases of pellagra.

Dr. John Harley said in both of Dr. Taylor's cases the nerve-lesions preceded the anæmia, and in the second case it was only a month before death that anæmia in a marked degree showed itself; so with other recorded cases. From this it appeared that the anæmia was merely the sequel. Did pernicious anæmia induce evidence of spinal-cord disease? In six cases of fatal anæmia which he had himself observed, there was no symptom of spinal disorder, though sprinkled hemorrhages were present in the retina and the serous membranes in all the cases. He therefore concluded that the association was merely accidental and not interdependent.

Dr. Gowers said the lines of degeneration found in these cases in the posterior column, or postero-median column, or in the lateral or anterior pyramidal tract, resembled in strict localization the lines of degeneration seen in tabes. In tabes there was a loss of the nutritional influence of the nerve-cells of the posterior ganglion, and so also in the case of action of all poisons like syphilis, alcohol, arsenic, lead, and possibly post-diphtheritic poison, and the posterior root fibres going from the skin and muscles to the posterior ganglia would also be affected. Those fibres, he repeated, which were under the nutritional influences of the cells of the posterior ganglion were especially susceptible to most poisons, but the fibres of the pyramidal tract were susceptible to only some of these poisons. In all these instances the sclerosis was a secondary overgrowth of tissue revealed by negative staining in the specimens which had been exhibited, or they could be revealed by positive staining with carmine. That there must be a toxic agent at work must be admitted, but whether the same toxic agent was the cause of the pernicious anæmia it was not possible to say. In pernicious anæmia there was found structural change in the blood-forming organs, such as the marrow and the spleen. Could such changes occur without causing also a profound change in the chemical processes of such blood-making organs? It should be remembered in this connection that the ferment from the diphtheria-organisms had been shown to transform the proteid material of the spleen into a poison which acted upon nervous tissues, and among other effects produced symptoms much like those of pernicious anæmia, only more acute. With such a perversion of the process of formation of the blood-corpuscles he maintained there would be perversion of the chemical constitution of the albuminous substances of the blood, with the result that a toxic agent would be produced capable of acting on the nervous system in the special way characteristic of such toxic agents. In this way a side-light was thrown on these affections—on the way in which the sufferer only rose to fall again. Whenever the toxic agent accumulated, vomiting and diarrhœa occurred and with it prostration, which ultimately proved fatal.

Dr. W. Hunter said he agreed with Dr. Gowers that a toxic agent played a considerable part in the production of pernicious anæmia and thought this agent was due to the absorption of poison of a specific nature from the intestinal tract. From the cases related it was not clear that the relation between the anæmia and the cord changes was a close one, for the cord changes appeared to be antecedent to the anæmia, and in one of the cases the evidence that it was really one of pernicious anæmia was not conclusive. The degenerative changes in the nervous system might either be due to some toxic changes in the blood or to hemorrhages. He favored the view of the lesions being hemorrhagic in origin, because in cases of pernicious anæmia these changes were few and far between, and recovery from the lesions was good.

Dr. Buzzard doubted whether the anæmia could be a cause of cord changes. In cases of ordinary chloro-anæmia functional troubles referable to the spinal cord were not uncommon, and disappeared when the anæmia passed away; in other words, they were temporary and functional. He mentioned cases in which grave nervous symptoms rapidly passed off under treatment.

Dr. Mott mentioned a case of pernicious anæmia in which the blood corpuscles were reduced to four hundred thousand per cubic millimetre; the knee-jerks were increased, but there were no signs of spinal-cord degeneration. At the necropsy there was found fatty degeneration of the pyramidal cells of the cerebral cortex; possibly later there would have been changes in the crossed pyramidal tracts.

Dr. Bowman said he had examined five cases of pernicious anæmia, and in none of them was affection of the nervous system noted as being present during life. He examined the spinal cords of three of these cases, but no degeneration was found to be present either in the cord itself or in the posterior nerve-roots, though Minnich found changes in the cord in five cases out of twelve in which there had been no nerve-symptoms.

Dr. Ormerod said neither pernicious anæmia nor the form of spinal-cord disease described was so common as to warrant the belief that the association between them was a mere chance one. Their symmetry of the specimens was against the idea of their being due to hemorrhage. He examined a case under the care of Dr. Church in which there was a lesion like that shown, but in that case no anæmia was present. There were very few cases of pernicious anæmia which were not treated with arsenic, and it had been shown that arsenic itself might produce similar lesions.

Dr. Taylor, in reply, said that in one recorded case the knee-jerk was at first exaggerated, then it disappeared, and then came back again. The cases were too numerous to be explained by coincidence merely.

Pernicious anæmia he thought was at present an indistinct entity, and so he described his cases as profound anæmia, as one of Dr. Putnam's cases was called.

SMALL-POX WITHOUT KNOWN EXPOSURE —A VOICE FROM INDIA.

To the Editor of the Medical Record.

Sir: As I would like some light thrown on incidental questions arising from the following history I trust this letter will merit insertion in an early issue of your journal. Though I am no advocate for the "coddling system," still no man can be more careful of his children than I am of mine. In January of this year my girl, aged six, took measles and had barely pulled through, when her brother, aged two years, was down with the same thing. How were the measles introduced? The drains, rooms, and compound of my house are kept scrupulously clean, and except in company with their mother or myself the children were not allowed outside my gates. I was not treating any case of measles

nor did anyone visiting me live in or come from an infected area.

During the children's illness, my wife (nigh two months *enceinte* and six times re-vaccinated) nursed the little ones, never leaving them for a minute nor coming out of their room, and declining to receive those of her lady friends who called on her. Three days after my son was convalescent, but still kept inside the room, the mother complained of severe lumbar and uterine pains with a slight discharge of blood, but as there was no rise of temperature threatening abortion, the result of mental anxiety and physical overfatigue was suspected and guarded against. The following morning pains had disappeared, and the temperature fell to 97.6° F., but at eleven A.M. it suddenly rose to 102.4° F., and by evening ascended to 105.8° F., accompanied by delirium. The next day's temperature averaged 104° F., fluctuating concertina-wise from 102° F. to 105. 4° F., and the following day she was covered from scalp to sole of foot with an eruption of confluent small-pox. On the eighth day about 5.5 ounces of partially organized blood-clot came away with a sharp pain which almost immediately ceased—examination was not practicable. Two days later, while in the act of vomiting, she felt a strong uterine pain, and a well-developed two-months' fœtus being expelled, the pains entirely ceased, the os contracted firmly, there was no hemorrhage and the temperature ran up to 103.8° F.; but there was no delirium and no lochia.

On the thirteenth day she had an inordinate thirst, not accounted for by the low temperature (97.2° F.), and regular though slow pulse (68); but toward noon the thermometer showed an increase of two degrees only, the pulse quickened to 118, and there were strong bearing-down and dilating pains, resulting in the discharge of a 8.75 ounces oblong and partially ruptured placenta, and a copious dark colored and high-odored flooding, which latter was controlled by free irrigation with boiled water cooled down to 108° F. She was twenty-four days in bed, during the whole of which time she was exclusively fed on boiled undiluted cow's milk, and with the exception of the belladonna prescribed when threatening abortion was suspected, the only medicine given her was prepared variola lymph, under which, for the last ten days of her illness, her temperature did not rise above 97.4° F. With the exception of a few reddish blotches that are rapidly fading away she is not at all marked, and though in 1886 she was for some time an in-patient at the Calcutta General Hospital for phthisis pulmonalis, her lungs are perfectly sound, and there were no chest complications during or after this attack of small-pox.

What I would like to know are: 1. For what period vaccination protects and at what invervals re-vaccination is necessary. 2. Never having left the room in which she was attending two cases of measles, how did my wife contract small-pox, to the infection of which she was not exposed at any time? 3. In epidemics what originates the nucleus or the first case? 4. Are the microbes of each eruptive disease specific to itself or are they homogeneous and capable of producing each other in the same subject, or appearing in one form in one subject and in another form in another subject exposed to the contagion or infection of the first? 5. What started the measles? 6. In what manner the small-pox manifestation stimulated the uterus to discharge its contents? 7. How the presence is to be accounted for of the partly organized blood-clot which weighed five and a half ounces (*i.e.*, 2,640 grains)? 8. The reason of the abortion taking three distinct stages at long intervals, and with a total cessation of pains and contraction on itself of the os uteri between each stage? 9. The fœtus weighs 175 grains, and the placenta 4,200 grains. They parted company, and for three days the latter (which more or less plays the part of a sponge) remained in utero, but had no cord attached to it when discharged. Did nature ligate the cord by occlusion of the severed extremities of the vessels with subsequent complete shrinkage, and thus prevent bleeding till the placenta came away? I am, Yours, faithfully,

ROGER S. CHEW, M.D., C.M., M.
Late Analyst to the Corporation of Calcutta.

COCAINE INJECTIONS IN PLACE OF CASTRATION FOR ENLARGED PROSTATE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I notice an article in the MEDICAL RECORD of April 6th, entitled "Warning Against Castration for Prostatic Enlargement." For many years the difficulty of enlarged prostate has been to me one of considerable importance. Castration is probably the least desirable operation in operative surgery, not because of the difficulties or dangers present in the removal of the testicles but because of the destruction of the virility of the individual concerned.

There is an old saying: "any port in a storm," and while in search for a remedy short of absolute castration I have devised a method that has so far succeeded in two cases. My method is to inject cocaine directly into the testicle twice per week for about two months. There is considerable absorption, spermatozoa cease to be produced in about six weeks; the patient gets immediate relief from the distressing symptoms of prostatitis and enlargement, the gland gradually shrinks to its normal size, and the finale of the case is recovery, with the power of copulation, but absolute cessation of the production of spermatozoa. Is not this better than castration?

S. E. MCCULLY, M.D.

CASTRATION FOR HYPERTROPHIED PROSTATE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Surgery has scarcely claimed the new territory of castration for enlarged prostate, when lo! a number of pessimistic shells are thrown into its camp. But the truth here, as always, must be fought out on neutral ground. We must carefully consider and weigh the import of the non-inflammatory and the inflammatory changes respectively, which the parietes of the bladder may have sustained. In other words, we must have a fair conception of the extent and duration of the vasomotor and the trophic disturbances that have taken place in the viscus. This is of the greatest practical moment in determining the outcome of the trouble. Whether success or failure will attend the removal of the prostatic obstruction, whether the bladder will be enabled to evacuate itself. In urethral obstruction, the capacity of the bladder is, in consequence of its hypertrophied muscular coat, as a rule, diminished. The hydrostatic tension being exerted on the urethra posteriorly to the obstruction dilating the canal until it finally yields so disastrously. The reverse obtains in prostatic obstruction. The capacity of the viscus, notwithstanding the thickening of its muscular walls, is, as a rule, materially increased. High tension exerts itself more on the vesical walls, and there exists, besides the post-prostatic pouch for the accumulation of residual urine, more or less atony of the entire organ, not to mention sacculation and the fatty changes which occur at this time of life. Then, add to these anatomical changes, the factors incident to prolonged inflammation, the extension of the process into the submucous tissue, where infiltration and organization take place, and when in consequence the bladder walls are rendered inflexible and indurated, and the hypertrophied muscular coat is unable to obliterate its cavity. I am citing ancient his-

tory which every pathologist will verify. No wonder that, in these cases, relieving the vesical outlet of the embarrassment by causing atrophy of the prostate or by removing considerable portions of the gland as in prostatectomy, with the additional advantage of rest and drainage, the patient fails to obtain material benefit. But in properly selected cases, and when timely undertaken, the operation has not only made its advent, but, I believe, has come to stay, for a time at least, until we find something better. Men who have symptoms of prostatic obstruction will have very little use for their testicles in the time to come, and they should be impressed with the adage that applies to them, *par excellence*, that "coming events cast their shadows before." They will thus avoid the annoyance, the distress, the misery that inevitably awaits them.

Truly yours,
ALEXANDER W. STEIN, M.D.

VIEWS ON ANTITOXIN.

To the Editor of the Medical Record.

SIR: I was very much pleased with the remarks of Dr. Galloway in your issue of March 23d, most probably from the fact that they so closely coincide with my own views with respect to the too premature acceptance of the antitoxin treatment of diphtheria.

About twelve years ago there was an epidemic of diphtheria in a village in the vicinity of Halifax, N. S., and being a practitioner there at the time, I was called upon to attend 117 cases of the disease, out of which number I lost only 7. The treatment invariably used was locally, a solution containing liq. calcis sulphurata, turpentine and glycerine, while internally I used brandy and an emulsion of cod-liver oil with hypophosphites.

The seven cases that died were diphtheritic croup; in those that recovered the disease did not extend beyond the throat and tonsils. I state this fact because I am not advocating any theory or method of treatment, and desire to show that other forms of treatment are attended with as satisfactory results as those obtained by the antitoxin treatment.

I sincerely hope that the serum therapists to whom, in a measure, I strongly incline, or any other therapist, may be able to discover antidotes not only to diphtheria, but to every other fatal disease, and I even go so far as to say I believe such antidotes will some day be found, but I do not think the facts so far shown will warrant us in accepting antitoxin as an absolute antidote to diphtheria any more than Koch's lymph was an antidote to consumption, or Brown-Séquard's elixir was an antidote to old age.

JOHN A. LANIGAN, M.D.

NIAGARA FALLS, N. Y.

TO PREVENT SUBSTITUTION.

To the Editor of the Medical Record.

SIR: Some of our medical friends have been making vigorous protests of late against "substitution by druggists," and usually in such a way as to indicate their own lack of exact knowledge of the subject. Having "slaved" in pharmacy some ten years prior to attaining the honor of M.D., the subject of "Substitution" is to me a familiar one from both sides.

Allow me therefore to state most emphatically that the crime of substitution is almost an unheard-of thing in the entire line of United States Pharmacopœia preparations, with the rare exception that the pharmacist may use his own or some other make of fluid extract, tincture, or elixir than the particular make specified. For such a substitution there is little or no justification—yet I question if the doctor who will prescribe Smith's, Jones's, Brown's, or some other fellow's elixir, essence, or powder (nearly all of which are strictly proprietary medicines), has so highly honored himself that he is in a position to throw stones at the druggist for yielding to the temptation to dispense "his own" preparation!

Now, some of these proprietary remedies are very fine pharmaceutical products, and a few of them could be named which are of such high quality as to defy imitation or substitution, and a respectable druggist would no more think of substituting in such cases, than he would of dispensing commercial chloroform for Dr. Squibb's preparation.

All of these manufacturers request the doctor to "please specify *our* preparation on your prescriptions," and if he fails to do so he cannot fairly censure the druggist for dispensing his own article.

Every doctor should carefully select one or more reliable pharmacists, and have all his prescriptions filled there as far as possible, thereby insuring a better understanding of what the doctor wants, uniformity of dispensing, and ready accessibility in case of any misunderstanding. The more highly a doctor values his reputation and the paper which bears his signature, the more careful he will be in the selection of a druggist, for the plain truth is that there are quacks and deceivers in pharmacy just as there are in medicine, both equally unprincipled. When the doctor knows his prescription is to be filled in some other city, if he wishes some particular preparation, he should so specify, and the prescription will be dispensed exactly alike in every first-class pharmacy in the United States.

The more thoroughly a patient is convinced of the value of the doctor's advice and prescription, the more careful he will be in selecting a druggist to carefully dispense a remedy. G. W. WHITFIELD, M.D.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 20, 1895.

	Cases.	Deaths.
Tuberculosis	156	115
Typhoid fever	5	4
Scarlet fever	92	10
Cerebro-spinal meningitis	3	4
Measles	231	31
Diphtheria	222	43

Is Pyrexia a Friend or an Enemy?—The etiology, significance, and treatment of pyrexia is a stock subject of observation and discussion. It comes up again and again with the persistence of a poor relation, yet the opportuneness of its importunity can never be denied, seeing that we are still without a working hypothesis in respect of the causation and significance of fever. Should we, like our forefathers, see in fever a humor akin to a demon, fit only to be combated and exorcised by all and every means in our power, or ought we, as more recent observations would seem to indicate, to view fever in the light of a willing ally against the marauding and ubiquitous bacillus with its train of excrementitial toxins? That is the question, as Shakespeare once observed under slightly different circumstances. If pyrexia did not have some beneficial effects as in some way an obstacle to the bacterial invasion it would not, as was urged by an ingenious but somewhat too hypothetical speaker, have been perpetuated in the animal organism. Most of nature's reactions are purposive, and, as we have failed in our efforts to suppress fever, we may well ask ourselves whether or not the rise of temperature which characterizes all acute specific affections does not, like

abscess formation in response to local irritation, tend to prevent the further elaboration of lethal processes? We know that, as a general rule, pathogenic bacilli can best be cultivated at the normal or a slightly lower temperature. We know, too, that variations of temperature within comparatively narrow limits seriously interfere with their development and proliferation. This fact alone affords matter for reflection. May it not be that the stimulation of the thermogenic centres is one of nature's means of combating the evil genii in the shape of microbes which secrete the poisonous toxins, with the elaboration of which the pyrexial process is so closely associated? Is pyrexia, and, if need be, hyperpyrexia, not an attempt to sterilize the blood and the tissues of the agents that are working havoc therein? In considering the question of the thermometric phenomena associated with the specific fevers, we must, indeed, bear in mind that a certain comparatively high temperature is as natural to a given diseased condition as is a normal temperature in health. A man afflicted with a pneumonia may really be more ill with a low temperature than when he presents the pyrexial phenomena usually associated with that disease. It is obvious on the face of it, that the therapeutical indications in respect of fever are less simple and straightened than they appear at first sight, and these considerations serve to emphasize the difference in the action of the two great classes of antipyretic agents—those which act directly on the thermogenic centre, and those which merely reduce the surface temperature, and prevent the accumulation of heat within the organism. If a rise of temperature really represents an effort on the part of nature to lessen the biological activity of the invading organs, we must be rendering sorry service by diminishing the irritability of the thermogenic centre in response to the stimulus given by the enemy. The result of antipyretic treatment, strictly so-called, tends to support this view. Professional opinion at the present time tends to discount the indiscriminate use of drugs of the antipyrine class for the purpose of reducing temperature. The patient, after the artificially induced fall of temperature, is often worse off than when the fever was in full swing, and grave symptoms often accompany, and may even be said to measure the efficacy, of the antipyretic medication. An exception may, perhaps, be made in favor of drugs of the quinine-salicylic group which have a thermolytic effect in virtue of their bactericidal action. Quinine, for example, is most efficacious in suppressing malarial fever when given some hours before the attack, at a time when the temperature is subnormal. It is, therefore, less a thermolytic than a microbicide. It is hardly necessary to promise that purely clinical observation cannot be implicitly relied upon, for the data which it affords are conflicting, incomplete, and inconclusive. Our forefathers bled for fever, and in so doing they were, possibly unconsciously, acting on strictly logical principles. To withdraw a certain proportion of the microbe-laden blood from the organism is to reduce pro tanto the disease-producing causes, just as in local tuberculosis we seek to minimize the risk of generalization by the ablation of all accessible foci or infection.

Venesection is out of date, and medicinal antipyresis has taken its place, but there are grounds for suspecting that the results are, to put it mildly, not more satisfactory, and public opinion is just now somewhat hostile to this empirical meddling with the action of the vital centres. No such difference prevails in respect of what may be termed the external method of thermolysis—by cold baths, wet packs, and the like. Any evil effects dependent on recourse thereto can easily be avoided or averted by the careful application of common-sense principles. In future, it may well be that true wisdom may consist in treating fever as a valuable friend and ally, rather than as an enemy to be fought at the expense of the organism.—*Medical Press.*

Mental Therapeutics.—The therapeutic influence of credulity raises a not unimportant question in medical practice—namely, how far it is justifiable for the practitioner to go in certain cases in conscious deception of the patient. It may be said that the end to be obtained justifies the adoption of any and every means that can be brought to bear; but the matter has another side to it. A blind belief in the powers of medical art has been transmitted from the days when magic and medicine were almost synonymous terms; and it is questionable whether it is really justifiable to encourage this kind of belief, except in circumstances such as our correspondent describes; and even then it is not certain that another line might not have been followed by success. It is doubtless more difficult often to strengthen the will-power of such an invalid than to yield to her credulity, but there can be no two opinions as to which line of action would be of most value to her mental health.

Medical Life Peers.—Dr. Eduard Albert, Professor of Clinical Surgery, and Dr. Hermann Freiherr von Widerhofer, Professor of Children's Diseases in the University of Vienna, have been created life members of the Austrian House of Lords. The other representatives of medicine in the Austrian Upper House are Dr. Ernst Ludwig, Professor of Medical Chemistry, and Dr. Schneider, both of whom are also members of the Aulic, or Privy, Council. It may be mentioned that the Austrian Herrenhaus is composed of princes of the Imperial family, nobles with the hereditary right to sit, archbishops, and life members nominated by the Emperor.

The Roumanian Faculty of Medicine has refused to allow Madame Sacara Tulbure to compete for the vacant professorship of children's diseases, on the ground that the university is represented in the senate by one of its number elected by the faculty; but women cannot vote, hence Dr. Tulbure could not exercise all her duties if appointed professor; therefore evidently it would be wrong to expose her to the danger of being elected professor. That this danger would arise if she should compete, was shown by the fact that she had already been granted a travelling fellowship by the Roumanian Government because of her brilliant work as a student of medicine.

A Malarial Map of Italy has recently been issued by the Italian Bureau of Statistics. It is based upon the death returns during the years 1890–92. The varying intensity of the disease in different sections is shown by modifications of color. In the three years there were 50,000 deaths from malarial causes, or 54 in 100,000. The worst districts, where the mortality is as high as 8 in 1,000, are in Southwestern Sardinia, Southeastern Sicily, the Pontine marshes, the district at the head of the Gulf of Taranto, and the southeastern slope, from the promontory of Gargano south to the Ionian Sea. Districts where malaria prevails, but not so intensely as to be fatal, are the lower reaches of the Po, Grosseto in Tuscany, the mouth of the Tiber, and the district near Salerno and the temples of Paestum. In Rome itself, malaria has sensibly declined; the deaths in 1881 were 600, in 1892 only 139. The general mortality from this cause in Italy has remained pretty constant; the average is 15 or 18 per 100,000.

Wrisberg's Cartilage.—Professor Bernhardt Fraenkel, of Berlin, has recently pointed out that the little wedge-shaped cartilage in the ary-epiglottic fold, generally known by the name of Wrisberg, was really first described by Morgagni, in his *Adversaria Anatomica*. It was subsequently rediscovered—apparently, quite independently—by the celebrated Dutch anatomist, Peter Camper (1770). Dr. Fraenkel, therefore, thinks it would be well to drop the eponymous designation and call the cartilage simply "cuneiform," as was proposed by Cuvier.

FURTHER IMPROVEMENTS IN MICROSCOPICAL TECHNIQUE.[1]

BY HENRY G. PIFFARD, A.M., M.D.,

PROFESSOR OF DERMATOLOGY, UNIVERSITY OF THE CITY OF NEW YORK.

IN the *New York Medical Journal* for July 16, 1892, I published the description of an electrical illuminator for use with the microscope. The lamp was an incandescent, with cylindric bulb about three inches in length, and furnished with a short, and comparatively thick, carbon filament, supported in position by copper wires.

To bring the lamp to proper incandescence a current of three ampères, with pressure of fifteen volts, is requisite; and under these conditions it emits a light of fifteen candle-power. If the lamp were directly connected with the Edison service current of 120 volts it would be instantly destroyed by the excessive pressure, just as a water-pipe, intended to support a given pressure, would burst if subjected to a much higher one. The means first adopted by me to obviate this inconvenience was the insertion of a proper resistance-lamp in series with the illuminator. The lamps furnished at the beginning were quite satisfactory, but later I found great difficulty in obtaining them of uniform resistance and voltage. This, on the whole, was rather fortunate, as it compelled me to look elsewhere for some other means to effect the same result. This I found in a Carpenter rheostat, which not only answers the purpose in the most satisfactory manner, but possesses certain special advantages in addition. The object of the lamp here described was to obtain critical illumination under the best conditions and with the least inconvenience. (The lamps and rheostat can be obtained from The General Electric Company, New York.)

Microscopical illumination is said to be critical when the minified image of the radiant coincides in plane with the object under examination; in simpler words, when the lamp-flame is focussed on the object. The means most commonly employed to obtain critical illumination by expert microscopists is the use of the narrow edge of a small (half-inch) kerosene flame, such as is furnished by the Beck (English) and Acme (American) and other microscope lamps. The rays from this flame should be parallelized by a suitable convex lens, and then focussed by the concave mirror (without condenser) or with plain mirror and achromatic condenser.[2] The advantages of critical illumination reside in the fact that in many cases fine details of structure are displayed to better advantage than when the light is not critical.

Referring again to the rheostat, the one here used contains twelve steps or grades of resistance, the maximum being forty ohms. With the entire resistance in circuit the lamp burns with a fairly bright light of slight yellowish tint. As the arm is moved forward step by step the light increases in brilliance until the sixth step is reached, at which point the intensity becomes dazzling and beyond which it is not prudent to go, that is if the life of the lamp is to be preserved for any length of time.

The quantity of light thrown on any subject under examination varies with the quantity emitted from the original source, controlled in turn by the diameter of the diaphragm, the intensity of the light remaining the same; and it is well known that certain objects become visible only when the quantity of light is diminished by a small diaphragm. When the intensity varies, however, the case is quite different, for we find that in a large proportion of objects fine detail is displayed to better advantage by increase rather that diminution of the intensity. This opens a field of investigation in connection with microscopical illumination that has not been, so far as I am aware, hitherto explored. My own experience with it, limited to a few months only, is insufficient to enable me to speak in detail of all the benefits that may be derived from having the variation of intensity under such perfect control. I am satisfied, however, if the working microscopist once has this means of control at his command he will never afterward willingly give it up. My personal experience, moreover, is in full accord with theory. With light of lower intensity there is a larger relative proportion of rays of long wave-length, while with the higher intensity the light contains fewer rays of long wave-length and a relatively larger number of those of short wave-length. The symbol λ is usually employed to indicate the wave-length, and we have the equation $Rp = \frac{2\,N.A.}{\lambda}$. In other words Rp (resolving power) is greater as λ (wave-length) becomes smaller. For definition I prefer the longer wave-lengths; but for resolution the shorter ones are more effective. I therefore offer the arrangement here described as a distinct improvement over our present methods of microscopical illumination so far as the use of the artificial light is concerned.

In the *American Journal of the Medical Sciences* for July, 1893, I called attention to the advantages that would accrue both in visual and photo-micrographic work from having the objective corrected specially for the D line of the spectrum rather than for the shorter wave-lengths (F to G lines). Such lenses, performing in the most satisfactory manner, have been made for me and for others by Spencer, Gundlach, Bausch & Lomb, and Leitz, and can be obtained from them on special order.

In the MEDICAL RECORD of March 24, 1894, I described "A simple means of increasing the aperture and improving the performance of some immersion lenses." The lenses referred to were some English water-immersions, and certain oil-immersions of American make. The means adopted consisted simply in substituting the mono-bromide of naphthalin for the water or oil which the makers had originally intended to be used with their respective lenses. This substitution necessarily introduced a high degree of negative spherical aberration, which in turn was corrected by closing the systems and shortening the tube-length. By this means the numerical aperture was increased in the water-immersions in the ratio of 1.33 to 1.65, and in the oil-immersions in the ratio of 1.52 to 1.65. I further proposed that the opticians construct objectives primarily intended for use with the mono-bromide, but which could, if necessary, be used with oil. Dr. Dallinger, in the *Journal of the Royal Microscopical So-*

[1] Read before the New York Academy of Medicine, April 18, 1895.

[2] Critical illumination cannot be obtained when using the chromatic or so-called Abbe condenser.

ciety, has criticised this idea unfavorably and irrelevantly, but I believe that if he makes the necessary practical tests he will change his views. I also communicated the idea here stated to a practical German optician of world-wide fame. The reply from Germany was definite and clear, and to the effect that the thing could not be done; that a lens could not be constructed that would work with mono-bromide, unless it was used in connection with objects mounted in media of high index on flint-glass slides and with flint-glass covers.[1]

A number of important improvements in connection with microscopy have been accomplished by American investigators, but almost without exception they have been received with ridicule and incredulity abroad. When many years ago the late Charles A. Spencer stated that he was able to construct well corrected objectives with an angular aperture exceeding 170°, the foreign criticisms were to the effect that he was either mendacious, or else that he did not know how to measure angular apertures. All the same, he sent a lens to England, the angle was measured and his statements confirmed.

When, a few years later the late Robert Tolles declared he had constructed a lens which practically possessed a higher aperture than that of the highest possible theoretical angle (180°) his statements were met with substantially the same reception. To-day we have in common use as the outcome of Tolles's ideas lenses with a numerical aperture from thirty to fifty per cent. higher than is possible with any dry lens possessing an angle of approximately 180°.

When also the late Colonel J. J. Woodward, M.D., asserted that he had resolved certain of Nobert's test-lines that had baffled European ingenuity, his reception was equally inhospitable. His photo-micrographs, however, settled the question.

Cognizant of the experience of other American investigators, I was quite prepared to encounter hostile criticism, but must confess I had some slight curiosity to learn the exact form it would take. I then conferred with an American optician, Mr. Herbert R. Spencer, of Buffalo, who constructed for me a special mono-bromide of naphthalin immersion lens to my entire satisfaction, and I will later show you (on the screen) a photo-micrograph taken with it of the well-known test object the Pleurosigma angulatum. The object was an ordinary commercial Möller slide, attached to a crown-glass cover and mounted on a crown-glass slide, and in a medium of low index, namely air (n = 1). This absolutely disproved the validity of the German criticism.

In my article in the MEDICAL RECORD (*loc. cit.*) referring to substage condensers I wrote as follows: "The only existing strictly high-grade condensers that I know of are the achromatic and apochromatic condensers of N. A. 1.40 made by Powell & Lealand, of London. These will cost, laid down in New York, duty paid, about one hundred and twenty dollars each.[2] This price will prove prohibitory to many, and it is to be regretted that American opticians have not as yet found a way to produce a condenser of equal merit at a price that would bring it into more general use."

Since the above was written Spencer has accepted the challenge and supplied me with an achromatic condenser with N. A. 1.40, and at about half the cost of the English one. In its general performance and convenience of manipulation, it decidedly surpasses the Powell & Lealand achromatic N. A. 1.40 which I had at command for several months. Messrs. Watson & Sons, of London, recently informed me that they had just perfected an achromatic condenser with N. A. 1.25, but did not advise me as to the price.

In this connection I may be asked—what are the advantages that accrue from such large apertures in objectives and condensers? As regards objectives a twofold answer may be given. First: Resolution varies in direct ratio with the numerical aperture, the greater the aperture the greater the resolving power or ability to distinguish and separate small particles from each other. This is a demonstrable and demonstrated fact and cannot be gainsaid. Second: The greater the aperture the more truthful the image; *i.e.*, the closer the agreement between the virtual image and the geometrical form and dimensions of the object in gross and in detail. This is not a demonstrable fact, but is a deduction from Abbe's theories of microscopical vision, and must be accepted *pari passu* with them. To explain Abbe's theories in full with his demonstrations would require more space than can here be given. I shall offer, therefore, only a condensation from Davis.[1] This writer says:

"Professor Abbe tells us 'the very first step of every understanding of the microscope is, to abandon the gratuitous assumption of our ancestors, that microscopical vision is an imitation of macroscopical, and to become familiar with the idea that it is a thing *sui generis*, in regard to which nothing can be legitimately inferred from the optical phenomena connected with bodies of large size.'

"From the researches of Professor Helmholtz and Abbe, it has been clearly demonstrated that images of bodies of large size, when formed by lenses free from chromatic and spherical aberration, are in themselves geometrically correct pictures, truly resembling the objects themselves, were they enlarged to the same size and illuminated in a similar manner. Pictures formed in this way are termed dioptric images. When, however, the object is made up of particles less than $\frac{1}{2500}$ of an inch separated from each other, it is no longer possible to depict such structure by ordinary dioptrical means. The resolution of structures made up of particles having smaller intervening spaces than this is effected entirely by what is called 'diffraction,' the broad outline being, however, at the same time depicted by dioptrical rays. The light in its passage through the object is modified, or scattered, and produces what are called diffraction spectra, which may be easily seen in the microscope when proper means are taken for their exhibition. If the ultimate particles of the structure are comparatively large, the diffraction spectra will most probably all lie within the field of the objective, while if they are small they may produce such a wide dispersion of the interference-spectra that only a part of them may range within the field, the remainder being lost, owing to the aperture of the objective not being able to collect them. If only a portion of the diffraction spectra be collected by the eye-piece, it can scarcely be expected that the true structure is exhibited, and in fact this is the case, which can be easily exhibited by numerous experiments.

"Professor Abbe further says that very minute structural details, as a rule, 'cannot be interpreted as morphological, but only as physical characters: not as images of material forms, but as signs of material differences of the particles composing the object; so that nothing more can safely be inferred from the image as presented to the eye than the presence in the object of such structural peculiarities as will produce the particular diffraction phenomena on which the image depends."[2]

[1] "Der Vorschlag des Herren Professor Dr. Piffard wegen eines monobrom-Naphthalin objectives in zur ausfuehrung zu umständlich und solche waren auch in Gebrauch unpraktisch. Diejenigen welche von Zeiss angefertigt werden leiden ebenfals an diesem Fehler so mussen Z. B. Condenser, Deckglass, und vordeste Linse aus Schwersten flint-glass sein dito objectträger, und Einbettung in eine stark breckende Fluessigkeit (Realgar) was alles dem opticer die herstellung erschwert; und ein System in der angegehem Weise hergestelt wurde die Leistungen der heutigen Oel Immersionen nicht uerberbieten."

[2] They are a little cheaper now.

[1] Practical Microscopy, by George E. Davis, Am. Edition, 1889.

[2] Those desiring further information on this subject may consult Czapski: Theorie der optischen Instruments nach Abbe, Breslau, 1893.

The value of high aperture in dry as well as in immersion lenses, is, I believe, underestimated by many laboratory workers who have followed the teachings and practice of continental laboratories rather than the dicta of science in this respect. The students of diatomology first learned to appreciate these lenses in their own special work, but the histologists and pathologists, or rather the majority of them, fail to convince themselves of their utility. They labored under a mistaken idea that penetration and depth of focus was a *sine qua non*; and as the penetration varies inversely with the numerical aperture the lower rather than the higher ones were chosen. I allude more particularly to lenses of low and medium power, say from one inch to one-sixth inch equivalent focus. There were, however, two other reasons that kept the higher apertures out of the laboratory, namely their greater cost, and the fact that medium powers required careful adjustment for thickness of cover-glass in order to obtain the best results that the lens is capable of giving. A 10 or 12 mm. lens with an angular aperture of 100° (N. A. .76) is an unknown construction on the continent; but such lenses may be readily obtained from American and English opticians.

Professor J. Edwards Smith [1] was perhaps one of the first to insist on the advantages of high apertures in histological work, and he is ably seconded in more recent times by Dallinger.[2] I desire to add my own experience and testimony in the same direction.

As regards the desirability of high-apertured condensers it may be stated that they are necessary in connection with high apertured objectives; that is to say, if the full working capacity of the objective is to be utilized, and an achromatic condenser bears a similar relation to a non-achromatic "Abbe" that an achromatic objective does to the old style French non-achromatic triplet, such as microscopists of fifty or sixty years ago were in the habit of working with. It should be remembered, however, that the aperture of the condenser should not be disproportionately large as compared with that of the objectives. If you attempt to pour a quart of beer into a pint measure, you will surely disorder the table or the floor, and if you use a condenser of N. A. 1.40 with an objective of N. A. .70 you will disorder the image in like manner. The advantages of an achromatic condenser compared with an Abbe will be appreciated only by those who have used both. The confusion of light rays that come through an Abbe condenser (especially when using artificial light) are to me at least as disagreeable and fatiguing as a Babel of sounds would be to a sensitive ear.

In the MEDICAL RECORD (*loc. cit.*) I wrote as follows: "The increased visibility given to certain structures by the use of mounting media of high index is a subject that merits more attention than it has hitherto received, as it constitutes one of the factors that contributes to the best final result."

Diatom-workers have for years sought to improve their technique in this direction. Many diatoms are mounted "dry," that is, with air (n.=1) as the medium; glycerine (n.=1.46) is never employed; Canada balsam (n.=1.54) is largely used; styrax (n.=1.58) from the *Liquidambar orientalis* Miller, and liquidambar (from the *Liquidambar styraciflua* L., were found to be improvements; mono-bromide of naphthalin (n.=1.65 gave still better immediate results, but the mounts are difficult to keep; iodide of methyl almost impracticable in use; phosphorus (n.=2.22) is dangerous; stannous chloride dissolved in glycerine jelly [3] and realgar, both introduced by Professor Hamilton L. Smith, possessed very high indices, the latter approximating 2.40. The higher the index the more clearly the details of the diatom structure are shown, but as there are serious difficulties connected with the use of all the media of very high index, many diatom-mounters have adopted the mon-brom-balsam, as the medium best adapted to general routine use. This preparation consists of a solution of hard Canada balsam in mono-bromide of naphthalin, and the index will approximate 1.60, being a little higher or lower according to the proportion of the respective ingredients in the mixture.

In biological, histological, pathological, and bacteriological work, many of the media above named are impracticable, and the almost universal mountant is Canada balsam, thinned with turpentine, chloroform, benzol, or xylol.[1] A few experimenters looking for something better than balsam, have tried "mono-brom-balsam," but report it unsatisfactory.

Being fully aware of the advantages of some of the higher media in connection with diatoms, I have during the past three years given such time as I could spare to the search for better media for histological work. Styrax and liquidambar were tried and found better than balsam, but not quite good enough. Mono-brom-balsam was then employed, and exhibited manifold advantages over the others, exhibiting histological details and bacteria very much better than balsam, and not open to the objections (lack of permanency, loss of refractive index, etc.) that have been urged against it. For temporary mounts demanding immediate examination its advantages over the ordinary balsam are very evident. In connection with permanent mounts there is one inconvenience. The mixture dries very slowly, and even weeks after mounting the slightest force will displace the cover-glass from its position on the slide. The best procedure is to carefully centre the cover on the slide and then put it away for a week or two, after which adjust the slide on the turn-table and spin a ring of cement (shellac is best) around the edges of the cover.

Instead of using balsam dissolved in mono-bromide, a more desirable mixture, and one of higher index, may be prepared by substituting purified liquidambar for the balsam.[2]

The advantages of the latter preparation over the mono-brom-balsam are twofold: 1. When the liquidambar is mixed with mono-bromide of naphthalin in the same proportions as the balsam the refractive index is higher (n.=1.625) and we have increased visibility of minute bodies of lower index (tissues, bacteria, etc.).[3]

[1] How to See with the Microscope. Chicago, 1889.

[2] Carpenter: The Microscope and its Revelations, edited by Dallinger. London, 1891.

[3] Index will vary according to method of preparation.

[1] In one laboratory in this city glycerine is used to the exclusion of balsam, a procedure that, owing to the low refractive of the medium, is unphilosophical in the extreme.

[2] Purified liquidambar is not an article of commerce, but may be prepared in the following manner:

Procure a pound of the crude gum (an exudation from the *Liquidambar styraciflua* L., and put it in a water-bath to liquefy. Arrange also a Plantamour's jacketed funnel, with glass funnel inside, and two or three thicknesses of cheese-cloth. When the gum is sufficiently liquified, and the Plantamour funnel hot, proceed to filter. The filtrate should be received in a quart bottle. When cold add one pound of xylol. This should be mixed as thoroughly as possible with the filtered gum and well shaken with it several times a day for at least two weeks. At the end of this time filter the mixture two or three times through absorbent cotton or Swedish paper. The product will be a thin but perfectly clear and transparent fluid. This must now be concentrated by gentle heat, and the process may be considered complete when the warm liquid has about the consistency of thick molasses. When cold it forms a semi-solid mass extremely sticky and tenacious. Two parts of this should be mixed with three parts of mono-bromide of naphthalin, and a little gentle heat applied. The result will be a clear amber-colored fluid. Its refractive index should then be tested and brought to 1.625 by the further addition of whichever of the ingredients may be necessary.

Care should be taken to use the proper gum, as above indicated, which is the American "sweet gum;" and not the gum from either the *Styrax officinale* L., nor the *Liquidambar styraciflua* Miller.

As to the permanency of this preparation I can only say that I have mounts made with it two years ago which as yet show no signs of deterioration.

[3] The relation of the refractive index of the mounting medium to the indices of microscopic objects has not received the general attention it deserves. On this point Van Heurck, referring to diatoms writes as follows: "When any substance is immersed in a medium it becomes more or less visible according to the difference of their respective refractive indices. Taking the index of diatom silica at 1.43 and water at 1.33, the number ten will express the visibility of diatoms in water. Canada balsam has an index of 1.54, which would give eleven degrees of visibility. Pure styrax has an index of 1.60, and consequently the visibility would be 17, while mono-bromide of naphthalin

2. The mixture is more sticky and adhesive than the mono-brom-balsam, and the mount can be finished for permanent preservation in a shorter time.

In offering therefore the "naphthalin-ambar" I present it as the mounting media of highest index thus far produced, that can be put to practical use in bacteriological and histological work, and consequently the one best calculated to exhibit the intimate structure of this class of objects.

A very considerable portion of the laboratory work of the present day consists in the examination of sputum, and other bacterial mounts for diagnostic purposes only, and without any intention of preserving the slides. The medium most commonly employed in this connection is the ordinary immersion oil, with a refractive index of a little under 1.52.[1] A medium of higher index would bring the objects into sharper contrast. There are a number of essential oils that possess a higher index than cedar, and which can be used for this purpose, but I know of none that in this respect equals the oil of cassia. The oil is credited with an index of 1.605, but the index of the best sample that I have been able to obtain is 1.593. It is the product of the *Cinnamomum cassia* Blume, and is the official *Oleum cinnamomi* of the United States Pharmacopœia. It must not be confounded with the true cinnamon oil (from the *Cinnamomum Zeylanicum* Breyne, as this latter has a much lower index. There is little danger, however, of sophistication in this direction, as the Ceylon oil costs eight or ten times as much as the cassia. Bacilli examined in cassia exhibit an unrivalled brilliance and sharpness of contour; and the minuter details, such as spores, flagella, etc., are shown with a distinctness impossible in cedar oil. The oil of cassia, like the oil of cloves, tends to abstract the color from bacilli stained with some of the aniline dyes, but not with sufficient rapidity to interfere with the diagnostic examination.

Dr. Bowles Lee, in his most excellent "Microtomist's Vade-Mecum" (London, 1890), in his chapter on clearing agents, gives a list compiled from Stieda, of oils more or less used by histologists. He also quotes the researches of Neelsen and Shiefferdecker, who examined and experimented with a large number of essential oils, and who specially recommend the oils of cedar-wood, origanum, and sandal-wood.

I find that there is a marked lack of uniformity among workers as to their employment of clearing oils, many preferring, for some reason or another, the oils of cloves, bergamot, lavender, cajuput, etc., and the confusion of ideas on the subject is rather embarrassing to the beginner. This is due in great measure, I think, to the fact that the name under which any given oil is sold is by no means conclusive either as to its identity or purity. The oil of origanum, for instance, is mentioned in every work on histology and is found in every laboratory, and may be bought in open market at almost any price from thirty-five cents a pound to fifty cents an ounce. By the oil of origanum is meant the essential oil derived from the *Origanum vulgare* L. Desiring to obtain all possible information concerning this oil I turned to Flückiger and Hanbury's Pharmacographia and was surprised to find no mention of it in the index. Under another heading, however, I found the distinct statement that there is no oil of origanum in commerce. This Hanbury later confirms ("Science Papers," London, 1876), stating that the oil commonly sold under this name is in reality the red oil of thyme distilled in the south of France. Although it is exceedingly cheap it is liable to adulteration with turpentine. Mr. Hanbury, however, desired an absolutely authentic specimen of the true oil or origanum, and had the plant gathered and distilled for him in England. Seventy pounds of the plant yielded but one ounce of oil, concerning which he says:

"Contrasted with the oil of thyme the oil of origanum is distinguished by the following characteristics: 1. Odor, which is somewhat analogous to that of oil of peppermint, and entirely dissimilar from that of oil of thyme. 2. Color, which in oil of origanum is bright yellow, while the ordinary kind of oil of thyme is of a more or less deep reddish-brown."

It being quite clear that the substance sold as oil of origanum is not such, and it being equally certain that a good deal of the red oil of thyme is fraudulently sold under this name, the question may be asked whether there are any other sophistications to be guarded against. Some time since I procured a sample of what I believed to be genuine red oil of thyme, and found its refractive index to be 1.483, and also found it exceedingly undesirable as to a clearing agent in the limited range of tissues in which I tried it. Besides this, it presented marked differences in refractive index, and in other particulars, from several samples of "oil of origanum" with which I compared it. The only conclusion, therefore, that I have been able to draw is that there are a variety of oils sold under this name, and there is no certainty that any two workers may be using the same identical substance. There is, however, an essential oil derived from the *Origanum creticum* L., which some writers say is the proper one to employ. The refractive index of a specimen of this oil in my possession I find to be 1.492.[1]

Lee very properly says: "It would be important to possess a list of the exact indices of refraction of the substances used for clearing. I have unfortunately not been able to obtain sufficient information of a trustworthy nature for the compilation of such a list. Cedar oil has nearly the index of crown glass [this is true of the oil in the thick state to which it has been brought by exposure to the air, not of the thin, raw oil, which is less highly refractive], it therefore clears to the same extent as Canada balsam. Clove oil has a much higher index, and therefore clears more than balsam. Turpentine, bergamot oil, and creosote have much lower indices, and therefore clear less."

I most thoroughly indorse Dr. Lee's recommendation, but would go farther and advise a thorough restudy of our clearing media. Let whoever will undertake this research first procure samples of the various essential oils of unquestioned genuineness and purity. Next determine their refractive indices. Then, commencing with those of either highest or lowest index, ascertain and record their behavior with celloidin and paraffin sections, both as regards the simple tissues (connective, elastic, epithelial, glandular, etc.), and the compound ones, such as the skin. The oils found most desirable should then be carefully described so as to insure subsequent identification. Their color, consistence, specific gravity, and other physical peculiarities should be noted as well as their rotatory influence on polarized light. The determination of the refractive index is not alone sufficient for identification or test of purity; for instance, I have two specimens of cajuput oil that differ markedly in color, consistence, and behavior, and yet both possess the same index, namely, 1.465. It may be needless to say that the investigator should compare the data obtained by himself with the facts ascertained by prior workers, consulting freely

with an index of 1.66 would give a visibility of 22."—The Microscope, Antwerp, 1891.

This general rule applies not only to diatoms but to all other bodies that the microscopist has occasion to examine by transmitted light.

The determination of the refractive indices of oils and other fluids is so readily and quickly accomplished by means of the Abbe Refractometer, that one is surprised that this instrument is so little known and used in the laboratories for the purpose of standardizing their various media. It is made by Zeiss and sold in this city by Eimer & Amend. The German price is 260 marks.

[1] Zeiss standardizes his at 1.515, but I have found a striking lack of uniformity in the oils from other lens-makers, most of them being lower than this standard. If adjustable objectives are used this makes little difference as the lower index of the medium can be compensated for. If, however, the ordinary non-adjustable lenses are employed, the result will be an under-corrected, and consequently more or less untruthful image.

[1] Dr. Delafield has recently given me a sample marked Oleum origani cretici album, which has an index of 1.479.

existing literature, and particularly the writings of pharmacologists and physicists.

Whoever will undertake the study here outlined will without question deserve and receive the heartiest thanks of his co-workers in microscopy. The pathological thought of the times is exploring new avenues. In the days of the older pathologists we were content with the examination and study of morbid tissues in gross; later, with Virchow and his successors, we studied them more minutely, that is, the relation of the different tissues to each other. Now we seek to delve into the innermost recesses of the tissues themselves, and of the separate elements that compose them, and Metchnikoff has carried us still farther, even to the vital processes going on in the smaller living unicellular organisms. To investigate these to advantage one must avail himself of every optical aid that science places at his command.

10 West Thirty-fifth Street.

THE QUICK CURATIVE TREATMENT OF GONORRHŒA.

By FREDERICK A. LYONS, A.M., M.D.,

NEW YORK.

I believe it to be generally conceded all over the world at the present time that acute gonorrhœa is a specific disease, whose origin is the implantation on a mucous membrane of a pathogenic micro-organism, the gonococcus of Neisser. At any rate, those very rare cases of simple acute urethritis in which the gonococcus is not found are mild, non-contagious, require little or no treatment, and get well very quickly. I do not think it is stating it too strongly to say that in every case of acute urethral discharge the first thing to be done by a surgeon competent to treat the disease, is to prepare a slide from the urethral secretion and make a careful microscopical examination. This at once reveals the true nature of the disease, and settles the question whether or not the particular case in hand is of specific origin, and therefore due to contagion from another case of the same disease. It is my own decided conviction that if this were done, we should hear very few, or indeed no more such statements as the following. I quote from the most recent American text-book on surgery, published in 1894.[1] "Authentic cases are recorded of well-marked urethritis following accidental or experimental exposure to leucorrhœal discharges; to the secretion from an endo-cervicitis or endo-metritis (yes, if it contains the gonococcus) [parentheses my own]; to the discharge resulting from ulceration or malignant disease of the uterus; the menstrual fluid or acrid vaginal discharges; . . . and to many other undoubtedly non-specific causes."

The nature of the disease being settled, the next consideration is the prognosis and treatment. I need not spend a moment in enumerating the complications that are liable to arise, and often do appear, in what may seem at first, the most innocent case of clap. Swelled testicle, cystitis, retention of urine, stricture, surgical kidneys, etc. They are too well known. And what is the most enlightened and modern estimate of the duration of the best-managed case, free from complications and sequelæ? "In the most favorable event it requires a period of six weeks, a fact which it is well that the patient should be advised of beforehand."[2]

I believe that the method of treatment regarded as best, and pursued by the recognized authorities at the present time, is the symptomatic plan. "The only method of treatment that we practise at the present time is the methodical, local, symptomatic, and curative plan."[1] In this plan topical treatment finds no place until the acme of the disease has been passed, and is indeed regarded as being positively harmful when employed before that time. These ideas of treatment have been reached as the result of the failure of measures aimed at destroying the specific cause of the disease, the gonococcus, and it would further seem that the condition of the tissues produced by the irritation of topical remedies, rendered them a more favorable soil for the penetration and growth of the microbes. There can be no question of the fact that the ideal plan of curative treatment would be obtained, if, at the beginning of an acute gonorrhœa, scientifically demonstrated to be such by the proof of the presence of the gonococcus, we could apply a remedy which would effectually destroy the organisms, and thus remove the cause of future inflammation. It is a necessary condition that this should be effected without harmful destructive action on the tissues, the production of complications, or greater pain and discomfort to the patient than his disease would occasion.

I am as well aware as anyone that the so-called abortive treatment of gonorrhœa is a very old one, that numerous claims have been made to establish its feasibility, and that many plans have been put forward as sure and safe for its accomplishment. I am also aware that hitherto no such claim has been substantiated so far as to meet with general acceptance, and that the array of opponents in the hostile camp is more formidable in numbers and authority, and at the present period seem to be on the victorious side. The feud between the advocates of the abortive and conservative treatments is a very ancient one, has been very fiercely conducted, and is thought to have been buried out of sight long ago.

But let us see briefly what are the chief objections urged against a quick curative plan of treatment. They are mainly two. The first, a scientific consideration based on the pathogeny and pathology of the disease, and the second, a matter of clinical experience that the method not only fails to accomplish its purpose, having to be discontinued before the patient is cured on account of the pain and distressing symptoms to which it gives rise, but, likewise, is extremely apt to originate disagreeable complications. Let us turn our attention to the first.

It is claimed to have been shown by those who have recently studied the behavior of the gonococcus, that after having once gained a lodgement on the mucous membrane, it quickly penetrates first the upper layer of epithelial cells, then the lower, and with comparative rapidity the papillary body, and proceeds to proliferate, with astonishing fertility, in the upper layers of the sub-epithelial connective tissue. Finger claims the futility of any attempt to cut short the disease because of the rapidity of penetration of the gonococci; hence he says,[2] "We could expect success from those remedies alone which would destroy the entire epithelial layer, and would penetrate to the papillary bodies. Hence the damage would be much greater than the good to be derived from certain destruction of the gonococci." But is this really the case? Is the penetration of the cocci so rapid?

Finger, himself, says in another place, p. 88: "The opinion is beginning to prevail that the gonococci long remain upon the surface, and proliferate exclusively upon and between the upper layers of epithelium. This opinion is based upon a series of anatomical findings. These include the investigations of Toulon (1889), Jadassohn (1890), and Fabry (1891), on gonorrhœal para-urethritis; those of Rosinski (1891) on gonorrhœal aphthæ; and those of Toulon (1893) on gonorrhœal bartholinitis. In all these cases—and I have convinced myself of the correctness of the findings by examination of several para-urethral gonor-

[2] Gonorrhœa, by Dr. Ernest Finger. Third edition, p. 131. Wm. Wood & Co., 1894.

[1] Finger, loc. cit., p. 122.

[2] Loc. cit., p. 121.

rhœas—the gonococci proliferate exclusively upon the surface of the pavement epithelium, and form patches upon their uppermost layer."

From comparison of these two statements it must at least be conceded that it becomes a question of time alone, whether or not the gonococci can be reached while they are still proliferating on the surface epithelium. If so, they may be destroyed without injuring too seriously the entire thickness of epithelial covering. The period of incubation of the disease, the mucoid nature of the early discharge, the mild character of the first symptoms, and the weight of testimony, inclining to the verdict that the disease is well established before the cocci migrate into the sub-epithelial connective tissue, tend very strongly to confirm this idea.

What in effect is Crédé's method of preventing, and curing in its inception, ophthalmia neonatorum—a method that has saved the sight of innumerable eyes, but a rapid destruction of gonococci? And it was in blennorrhœa conjunctivæ neonatorum that Bumm's investigations on the rapid migration of the gonococci were made. It is on Bumm's theories that the scientific objection to an attempt at rapid cure is based. Crédé's results are a sufficient reply.

Now, as to the second objection—the clinical one. This is a much more difficult matter to discuss. Here the personal equation enters much more largely as a factor. Apparent facts are liable to different interpretations by different observers. The same method may be applied in totally different ways by different men, and results claimed are not so susceptible of proof by others. Statistics, which, notoriously, may be manipulated to show opposed conclusions, are brought forward and cited on one side or the other, sometimes to the utter confusion of both.

In the present instance it must be remembered that the mass of accusations, marshalled under the clinical aspect against a quick curative plan, were made before the study of the disease was placed upon a scientific foundation; and therefore must be received with great caution.

When pain, chordee, vesical tenesmus, etc., are known to be among the most frequent symptoms of the disease itself, is it proven that they are produced by an injection, because one has been given? When the stricture occurs, which is well recognized to have as its cause, in the vast majority of cases, a preceding acute or chronic gonorrhœa, is it a result of the injections that were given, because the case was treated in that way? Are periurethral abscesses, glandular inflammations, epididymitis, prostatitis, and cystitis caused only, or in most cases, by the severe method of treatment pursued, while they seldom or never occur in cases untreated or treated merely by the expectant plan? From the very nature of the case all these clinical matters are scarcely susceptible of rational proof or disproof, and it would be useless here to seek the pros and cons on the subject as shown by the weight of clinical facts hitherto arrayed on one side or the other.

It appears to me that the proper course to substantiate what claim I have to make under the clinical aspect of this subject, can only be pursued by bringing forward the clinical facts put in my possession by my own observations on the cases that have come under my care. I claim no novelty of plan, procedure, or medicament; but I make the statement, and hope to vindicate it, that a quick, curative plan of treatment in acute gonorrhœa in its early stage, as I have used it, is not only practicable, but succeeds completely in a great many more than a majority of cases, is not deleterious in any, and has proven itself free from the danger of giving rise to serious consequences or sequelæ. I have, it is true, but a comparatively small parade of figures to present, but I hold that one case well observed and studied, will often afford as much knowledge on a given subject as one hundred. In such a matter there is no just parallel to seeking to place the status of a capital operation by obtaining the percentage from statistics of recoveries and deaths.

I will now explain the plan of treatment as it has finally been evolved, expose briefly its *rationale*, and then present the clinical facts on which my statements are based.

When a patient presents himself complaining of symptoms pointing to a urethral difficulty, I first get a detailed history of the case, and then on examination of the penis, smear a little of the secretion, if there be any, on a cover-glass. If there be none, or but a slight moisture, I rub the sterilized platinum wire with a little loop on it over about three-quarters of an inch of the walls of the urethra a few times, and smear this on a cover-glass. After staining in the usual way with methylene blue, I examine under an immersion lens. If gonococci are found and the history of the case shows it to be one of acute infection, and if there be a fair proportion of epithelial cells present in the secretion under the microscope, I deem it a good case for the quick curative plan of treatment, and proceed as follows:

Having had the patient urinate for the purpose of cleansing the canal, which I think is sufficient without further irrigation, I myself inject into the urethra, the patient being in the recumbent position, with an ordinary conical-shaped soft rubber pointed clap syringe, one drachm of a four per cent. solution of nitrate of silver. I seize the meatus on removing the syringe and hold the solution inside the urethra for from two to three minutes by the watch. The patient complains of none or but little pain at the time, and at most, according to my experience, a little smarting on urination during the next twenty-four hours, at the expiration of which time he is directed to present himself again. In the meantime he is cautioned to follow strictly the usual hygienic rules prescribed in these cases, and to do nothing more for himself whatever. When he presents himself again it will usually be found that the character of the discharge has changed to a thin serous fluid, a little more abundant than it was before, and on smearing the cover-glass and examining, it will be found that the gonococci have entirely disappeared or have been exceedingly reduced in numbers. If none are found two or three more cover-glasses are smeared and examined to make sure of the fact, and nothing more is done. The slight inflammation will then disappear in the course of twenty-four or forty-eight hours, but the secretion of the urethra is examined for several days until no more pus is present, and shows only normal epithelial cells, or as is sometimes the case, the ordinary bacteria that are commonly found in healthy urethræ.

If the gonococci have not entirely disappeared, the injection is repeated with a drachm of a two per cent. solution of silver nitrate, and in twenty-four hours a re-examination is made. The second injection produces a little more pain afterward than the first, and the secretion the next day is more serous, and perhaps tinged with blood; but I have not yet found a patient refuse a third injection when I have deemed it necessary with a one per cent. solution. If the gonococci have not entirely disappeared by this time, it is useless to proceed further, the treatment is abandoned for the time, and the symptomatic plan pursued; but, as will be seen later, so far as my cases show, the duration of every one of them has at least been materially shortened, and no more complications have ensued. The conditions at present accepted as necessary to the assertion of complete cure have been adopted in all cases, namely the absence of gonococci for a number of examinations, the absence of pus corpuscles, and periurethral complications.

A few words as to the *rationale*. Speaking of medicaments employed, Finger, page 114, says: "None has been employed so much, has been extolled and deprecated so much as nitrate of silver, *the most effective of*

all" (italics mine). I certainly subscribe to this statement and have adopted its use. This metallic salt, according to Jerosch (1889), in solution of 1 to 1,000 kills the germ in cultures in two to three minutes. (Finger, p. 99.) But in the urethra some of it forms an insoluble albuminate with pus, blood, and the protoplasm of the cells and epithelium. The use of a drachm of four per cent. solution is more than sufficient for bactericidal purposes.

In the early stages of an acute infection the germs have pervaded the anterior portion of the urethra only, and consequently the simple injection by an ordinary penis syringe is all that is required to attack them.

Now in the natural processes of spontaneous reaction of the tissues against the invasion of the disease, the cocci are carried outward from the sub-epithelial connective tissues if they have already penetrated so far, or from the lower layers of the epithelium by the leucocytes, and the stream of serous fluid exuded from the congested capillaries and lymphatics which is a constant current pushing its way to the surface. It is a matter of observation in every case that the application of a powerful solution of silver nitrate increases the afflux of leucocytes and rapidly augments the quantity of serum passing from the vessels, changing a mucous or even a purulent secretion into a markedly serous one almost immediately. I think, therefore, that it is a fair interpretation of the *rationale* of the action of this medicament to say that it stimulates the natural reaction of the tissues against the disease to still greater activity in clearing themselves more rapidly and completely of the germs that it has not reached directly to destroy. Its action is, therefore, directly in line with the efforts of nature, and merely makes those efforts stronger, more certain, and more rapid.

This serous discharge caused by the action of silver nitrate likewise seems to be a very unfavorable culture medium for the gonococci. This latter view receives a certain amount of corroboration from the researches of Dr. Lemoyne de Martigny, as set forth in a recent thesis upheld before the Faculty of Medicine of Paris.[1] He is advocating the use of permanganate of potassium in gonorrhœa. "Permanganate of potassium, which is not absorbed, and does not act on the deep layers of the mucous membrane, determines, however, an œdematous swelling of the entire urethra and a serous discharge of variable duration. Now this serous medium on the mucous surface of the urethra, and even in the interior of the walls of the canal, is most unfavorable to the reproduction of the organism. By irrigations, the gonococci are washed away from the surface of the urethra; by the reaction produced by them they can no longer be cultivated and proliferate to any degree, and the organisms which are situated in the depths of the tissues are soon expelled by the serous flux." If this be true of potassium permanganate, the same effect is seen in a multiplied ratio with a strong solution of nitrate of silver.

We will now proceed to the exposition of the clinical facts at my disposal, as in the order indicated above. During the past eighteen months fifteen cases of acute gonorrhœa in males have presented themselves in my private practice, which is general surgical work. I give the brief histories of all of them, so that the proportion of complete or partial success may be fairly estimated. The microscopic slides are a portion of the record of every case, so that there is absolute demonstrative proof of every statement. I give the cases in chronological order.

Case I.—Mr. S. J——, aged fifty, bachelor, presented himself May 27, 1893. Has had several previous attacks of gonorrhœa, but no urethral difficulty of any kind in ten years. Suspicious connection three days previously. This morning, at rising, noticed slight burning pain on micturition, and during the day observed slight discharge. In the evening, at the time of consultation, there was slight pouting and redness at meatus, and a drop of muco-purulent secretion. Microscopical examination showed pus-cells, epithelial-cells, and numerous gonococci. Injected urethra after urination with a drachm of four per cent. solution of silver nitrate, and directed him to call again on the morning of the 29th. On that date reported he had experienced little or no inconvenience, and had attended to his business as usual. There was a slight serous discharge, showing pus and epithelial cells microscopically, but no gonococci. Nothing more was done for patient, and subsequent examinations showed no return of gonococci and complete disappearance of pus-cells. This case I regard as cured in one day.

Case II.—Mr. B. A——, aged thirty-five, bachelor, presented himself June 28, 1893. Had had a slight discharge for two or three days, which was increasing, with slightly painful micturition. Had had numerous previous attacks of clap, and had been treated for stricture, but had had no urethral difficulty for last three years. Microscopical examination revealed abundance of gonococci and epithelial scales with patches of them. After urination injected with four per cent. silver nitrate solution.

June 29th.—The discharge was abundant, but much more serous in character. A few gonococci present. Injected with two per cent. solution.

June 30th.—Discharge abundant and sero-sanguinolent; a few gonococci. Injected third time with one per cent. solution.

July 1st.—Slight swelling about glans, slight sero-sanguinolent discharge, no gonococci. Subsequent examinations for a number of days showed return of urethra to perfectly normal state, no return of gonococci, and rapid disappearance of pus-cells. I consider this as a case cured in three days.

Case III.—M. M——, aged thirty-six, married, presented himself October 18, 1893. Had had numerous previous attacks of gonorrhœa. Epididymitis on three previous occasions. Gleets lasting a year and a half at a time. Mostly always under the care of a physician for urethral trouble, but had been apparently perfectly well during the last five years since marriage. Had been drinking freely, and while intoxicated with companions, visited and cohabited with prostitute. Yesterday noticed familiar symptoms, but was unable to see me till to-day. Secretion muco-purulent. Slide shows pus, numerous gonococci, and plenty of epithelial-cells. Injected with one per cent. silver nitrate solution.

October 20th.—Gonococci very few in number. Repeated previous treatment.

October 21st.—Slight serous discharge. No gonococci. Subsequent examinations showed quick return to normal state, and no reappearance of gonococci. Case cured in three days.

Case IV.—C. J. F——, aged twenty-five, single, presented himself October 18, 1893. Has had two previous attacks of gonorrhœa, from the last of which he has been entirely well for six months. He was under my own care. Slight discharge, showing under microscope few gonococci. Injections October 18th, four per cent.; 19th, two per cent.; 20th, one per cent. solution silver nitrate.

October 21st.—Complains of a good deal of pain on urination; some swelling of glans and prepuce, and sanguinolent discharge. Used no further treatment, though a few gonococci are still present, except hot-water fomentations, and lot. plumb. et opii as a dressing. By the 24th everything had subsided, and the gonococci, to my astonishment, had disappeared, not to return, as subsequent examinations proved. Case cured in six days.

Case V.—L. P——, aged twenty-five, single, presented himself November 22, 1893. First attack of any venereal disease. Had connection on the 19th and two days later noticed pain and discharge. Microscope revealed large masses of gonococci free, and on

[1] Annals of Gynæcology and Pædiatry, January, 1895, p. 269.

the epithelial-cells of which there was a good number, and in the pus-cells. Gave an injection of a four per cent. solution silver nitrate.

November 23d.—Gonococci still present, and as he had experienced no pain or discomfort from the injection, repeated the four per cent. solution.

November 24th.—The character of the discharge, which was purulent, had not altered to a serous condition. This patient showed not much diminution in the number of gonococci present, and he was carried along under treatment, the details of which it is not necessary to go into; suffice it to say that it seemed a complete failure as far as quick cure was concerned. The tolerance of this man's urethra to strong silver nitrate injections was astonishing to behold. He urged me to give them when I was afraid they might do harm. He never suffered pain on urination, and the amount of discharge was light. Week after week passed, but he still had a drop of pus in the morning when he squeezed, but no other discomfort. So he went along under various forms of treatment until April, 1894, the fifth month of his disease. I had been noticing for some time on the slides gonococci more or less numerous, comparatively few pus-cells, but many large, flat epithelial-cells showing that they must come from near the meatus. One morning, in getting some secretion for the cover-glass, I noticed that the drop of pus did not come from the urethra at all, but from a point a good quarter of an inch inside the right lip of the meatus, and well down toward the floor of the urethra. There was no pouting or redness to the punctate opening which would have called attention to it on inspection of the urethra which had many times been made. By enlarging the opening I passed a probe down parallel to the urethra for a good inch and a half. The platinum wire introduced and smeared on a cover-glass showed numbers of gonococci, but scrapings from the urethra well down showed none. I opened the canal up thoroughly with a long narrow-bladed bistoury and touched the bottom with nitrate of silver fused on a silver probe. From that time on, no more gonococci were discovered about this patient, and a short time afterward he was dismissed cured. A couple of months later he got married, and both he and his wife have remained perfectly well. Now I firmly believe that this man's urethra was thoroughly cured early in the treatment, but unfortunately the infected para-urethral canal remained undiscovered for quite a period, and for that reason the case has to be set aside as a failure. Yet, when I observed the real cause of this, my confidence in the treatment was restored.

Case VI.—B. A——, the same individual as Case II. Presented himself February 4, 1894. Infection four days previously. Discharge light, slight burning. Gonococci abundant, free, in pus-cells and on epithelial-cells, which were plentiful. Injection of a four per cent. solution of silver nitrate. Did not return next day, but on February 6th; discharge serous and contains no gonococci. Repeated subsequent examinations failed to reveal any return, and patient was discharged when there was no more pus. Case cured in two days.

Case VII.—C. J. F——, the same individual as Case IV. Presented himself February 6, 1894. Infection four days previously. Discharge muco-purulent, fairly abundant. Gonococci very plentiful in pus-cells and free, few epithelial-cells. Injected a four per cent. silver nitrate solution. Patient complained somewhat next day after injection, and though gonococci were still present, yet fewer, nothing was done.

February 8th.—Again injected with a two per cent. solution of silver nitrate. Nothing more was done, and on the 11th no more gonococci were found. Subsequent examinations revealed no return, and in sufficient time patient was dismissed. Case cured in five days. An interesting episode connected with this case was as follows: The only woman whom he had had connection with, Mrs. B——, was married and living with her husband, so he was very much surprised to find himself in such condition. He accused her of the fact, which she indignantly denied, and she promised to call on me, firm in the purpose of confounding his impudence. She called on February 8th, first having fortified herself with the opinion of another physician, who, after an examination, had told her positively there was nothing the matter with her. On inspection there was nothing that would indicate her condition except a slight leucorrhœal discharge, and yet a smear from the sterilized platinum wire introduced into the urethra revealed swarms of gonococci; the uterine secretion contained the same. Glands of Bartholin negative. She claimed to have been perfectly well for the last two years, since she had been operated on for double pyosalpinx by Dr. Wylie of this city. She had been sick for three years previously with repeated attacks of pelvic peritonitis. She ridiculed my statement that there was anything the matter with her, and left in high dudgeon. Her subsequent history I know nothing of.

Case VIII.—F. W. W——, aged twenty-two, single. Presented himself February 28, 1894. First attack of any venereal disease. For the last ten days had had a profuse, greenish, purulent discharge, and severe pain on micturition. Had consulted no physician until he came to me. Examination revealed some œdema of prepuce with phimosis, painful condition of anterior portion of urethra, and profuse greenish, purulent discharge, which showed, microscopically, abundance of gonococci free, and in the pus-cells, few epithelial scales. In the light of my past experience, I had no fear of using a strong silver nitrate injection, and employed one of two per cent. in the usual way.

March 1st.—Discharge diminished in amount and much more serous in character. Great reduction in number of gonococci. Phimosis and œdema of prepuce slightly increased. No complaint of increased pain in urination. Injection of a two per cent. solution repeated.

March 2d.—Reduction in quantity of discharge. It is of a thin, serous quality, and under microscope showed remarkable diminution of gonococci with numerous blood-corpuscles. Nothing more was done.

March 3d.—Increase in discharge and number of gonococci. Absence of blood-corpuscles, œdema of prepuce reduced. Injected with two per cent. solution.

The patient did not return as directed, and I heard a few days later from a friend of his, that he considered himself well and did not think it necessary to come again. I cautioned him through his friend that likely he was mistaken. However, I heard nothing more of him till fifteen days later, when he returned on March 18th as bad as ever, with a profuse purulent discharge. He had been drinking with friends, and the discharge had reappeared the next day with pain. Examination showed abundance of gonococci free and in the pus-cells, and a larger number of epithelial-cells present than on the first occasion. I injected him three days in succession with a two per cent. solution, March 18th, 19th, 20th. March 21st the discharge was serous with a little blood, but there were no gonococci.

On March 25th a very few gonococci reappeared, and I injected him twice more between that time and April 1st, when they disappeared entirely and did not return. He was dismissed cured in a few days more, after repeated examinations.

It is difficult to place this case. I certainly think that had he returned as directed in the first instance, he would have been spared the subsequent sickness. But even as it was, his disease had only lasted four weeks from the time he came to see me, and of that time he had had two weeks of, what seemed to him, immunity. Certainly the symptomatic treatment does not show as good results.

Case IX.—W. B. H——, aged thirty, single. Presented himself with acute gonorrhœa March 23, 1894.

Patient had had several attacks of gonorrhœa and chronic urethritis, with constant gleety discharge for the last two years. Had been cut for stricture in the West a year ago, but with no relief. An examination showed stricture three inches down, calibre 22 French. Microscopically: Pus-cells and mucus, moderate quantity of epithelial-cells, and abundance of bacteria of great variety, among which were some that I think were gonococci—they were difficult of recognition. I would like to say, in passing, that I place no value whatever on Roux's method of differentiating gonococci; for, after making numerous experiments with it, I believe that gonococci do stain with Gram's method, though perhaps not so readily as some other bacteria. I operated upon him for stricture February 22, 1894, and in a short time freed him from discharge and his urethra from all pathogenic bacteria. On March 20th, two weeks after he considered himself perfectly well, he concluded to call on the fair sex once more, and appeared on the 23d to show me the result of his visit. Meatus reddened and pouting; sufficient muco-purulent discharge to drip, and burning pain on micturition. Slide showed abundance of gonococci free, and in the pus-cells, also on the epithelial-cells, of which there was a fair proportion. Injected four per cent. solution of silver nitrate in usual manner, and two per cent. solution on 24th.

March 25th.—The discharge was serous and sanguinolent, and he complained of quite severe pain, but no more than he had often experienced before with the clap. The slide showed pus-cells, epithelium, and red blood corpuscles (all of which were peculiarly pigmented), but no gonococci.

March 26th.—A few gonococci reappeared, and he was again injected with a two per cent. silver nitrate solution.

March 28th.—A one per cent. solution was again used, as a few cocci still persisted.

March 29th.—No gonococci were to be seen, nor did they reappear, and after repeated examinations patient was dismissed. Case cured in six days.

Case X.—Same individual as Case III., presented himself July 27, 1894. Had had muco-purulent discharge three days and considerable smarting. Slide showed abundance of gonococci free, in the pus-cells, and on the epithelial cells, which, however, were comparatively few in number. Injected four per cent. silver nitrate solution. This was repeated with two per cent. solution on the 28th, and one per cent. solution on the 29th.

July 30th.—Whatever secretion there was, was masked by blood, and the patient complained so bitterly of pain on micturition and partial retention of urine, that no further injection could be administered. The gonococci, however, were very few in number. Symptomatic treatment was resorted to, and in a couple of days all difficulty was gone.

August 2d.—There were no gonococci, but on the 3d a few reappeared. The patient was continued on symptomatic treatment till the 15th, when all gonococci had disappeared not to return, and after repeated examinations he was dismissed cured.

This case was of course a failure as far as quick cure is concerned, but nevertheless his disease lasted but eighteen days, which is a much better result than the symptomatic treatment shows.

Case XI.—W. S. C——, aged thirty-four, single. Patient presented himself September 5, 1894. Has had numerous previous attacks of gonorrhœa and gleet, and had stricture, for which he was under my own treatment, but has been perfectly well as far as the urethra was concerned for the last four years, to my own knowledge. Had connection with two different women within the last week, so cannot place the source of infection. Slight discharge and slight smarting. Slide showed pus-cells with gonococci in them, preponderance of epithelial-cells with plentiful gonococci proliferating on the surface. Injection four per cent. silver nitrate solution.

September 6th.—Discharge slight and serous, no gonococci. The cocci did not reappear, and patient discharged after repeated examinations. Case cured in one day.

Case XII.—S. D——, aged twenty-two, single, a very nervous individual, presented himself October 6, 1894. First attack of any venereal disease. Has had discharge and burning two days. Slide shows pus-cells with gonococci, and epithelium, moderately abundant, covered with large colonies of same. The cocci are extremely numerous. Injection with four per cent. solution silver nitrate.

October 7th.—Gonococci few, injection two per cent. solution.

October 8th.—Third injection one per cent. solution. Gonococci very few in number, but discharge not serous, and no blood. Patient complained of pain, and never having had clap before, had no experience of what usually accompanies the acute stage of that disease. He insisted on preferring a slower cure, so treatment was continued on the symptomatic plan. The cocci remained few in number and the discharge small in amount up to the 15th, when the discharge increased and the cocci likewise. At the end of the month the discharge declined. He visited me irregularly, but on December 18th there was no more discharge and absence of gonococci. After repeated examinations he was dismissed cured.

This case was a failure as far as quick cure was concerned, which, to some extent, was the patient's own fault, but it only lasted six weeks, and was certainly not aggravated by the early treatment. The woman, Miss C. U——, from whom the patient contracted his disease, was surprised when informed by him of his state, and immediately consulted a physician, who, she declares, examined her and informed her there was nothing the matter with her. She consented, however, to visit me, and though, on inspection, there was nothing but a slight leucorrhœal discharge, the secretion taken from the urethra and uterus with the sterilized platinum wire revealed abundant gonococci when examined under the microscope. Secretion from Bartholin's glands and vagina, negative. The patient informed me that two of his brothers cohabited with the same person on the same evening, and yet both escaped infection.

Case XIII.—W. B. H——, the same individual as Case IX., presented himself December 12, 1894. Has been perfectly well since he was last under treatment, eight months ago, though he has never evaded the allurements of promiscuous Venuses. Fair amount of muco-purulent discharge and pain. Slide shows abundant pus corpuscles filled with gonococci and fair number of epithelial cells studded with large colonies of the same. Injected four per cent. solution silver nitrate.

December 13th.—Discharge more serous and gonococci very few. Injected two per cent. solution.

December 14th.—Discharge quite serous, only a few pairs of gonococci, injected one per cent. solution.

December 15th.—Discharge sero-sanguinolent. Slide showed pus-cells much reduced in number, blood-cells, a few epithelial-cells, and no trace of cocci. They did not reappear, and patient dismissed after repeated examinations. Case cured in three days.

Case XIV.—W. S. C——, same individual as Case XI., presented himself December 23, 1894. Had been well since last attack, three months and a half ago. Infection four days previously. Slight amount of secretion, and slight pain. Slide showed great numbers of gonococci, free and in the pus-cells, also on the epithelial cells, which were in fair numbers. Injected four per cent solution silver nitrate.

December 24th.—Discharge serous, and contained no gonococci. Repeated examinations showed no more

cocci and rapid disappearance of pus-cells. Case cured in one day.

This case showed some points of interest and many of great suggestiveness, all of which, however, I have not time here to follow up. The man had been partially living for a number of months with one woman, Miss I. O——; but, just before the former occasion of illness, had stepped aside from the path of virtue, and been seduced by the charms of another fair one to whom he ascribed his misfortune. This time, however, there was but one party to blame, and at his solicitation she consented to visit me. She did so on December 27, 1894, and on examination I found in the vestibule, about a quarter of an inch below the urethra, a swollen para-urethral tubule with a perceptible opening reddened and slightly pouting. On pressing upward upon this through the vagina, about two good-sized drops of pus exuded. This, under the microscope, showed, among large numbers of a great variety of other bacteria, abundant gonococci. There was considerable muco-purulent discharge from the cervix, and this likewise revealed unmistakable gonococci free and in the cells. Secretion from the urethra and Bartholin's glands negative. Not having time to examine the slides at the moment, I requested her to call the next day. This she did, in company with the young man. She informed me, that, in the meantime, she had been to consult a physician who could tell by examination at once if there were anything the matter with a person, which every physician ought to be able to do, and he had assured her there was nothing wrong. I replied that my capacity did not go so far, but I was nevertheless sorry to inform her that she was suffering with gonorrhœal disease. A few days later, however, she concluded to call for treatment. I had no difficulty in destroying the source of infection in the vestibule, by running down to its bottom a probe on which I had fused some silver nitrate. After a few applications to the uterus, I found such treatment futile, and advised thorough curettement under ether. She agreed, and set the day. Consulting with some friends, however, she visited a third physician, who, on examination, informed her there was nothing the matter with her, but prescribed an alum injection. She, thinking, I presume, that the agreeable opinion of two physicians was better than the disagreeable assertion of one, failed to materialize again. I have heard since that she has had a slight attack of pelvic peritonitis.

Case XV.—J. C——, single, aged thirty-five. Previous attacks of gonorrhœa, but none for five years. Presented himself December 26, 1894. Suspected connection December 21st. This is the third day of pain and discharge, which is purulent and copious. Slide showed great numbers of gonococci free and in the pus-cells, blood-cells, and few epithelial cells bare of colonies. Injection, four per cent. silver nitrate solution.

December 27th.—Second injection, two per cent. solution.

December 28th.—Discharge more serous, but still purulent, not as many blood-cells, and but very few gonococci. Third injection, one per cent. solution.

December 29th.—Discharge sero-sanguinolent, quite a number of blood-cells, but very few gonococci. Patient complained of a good deal of pain, so symptomatic treatment was directed.

January 3, 1895.—All acute symptoms subsided, but gonococci increased in numbers.

January 11th.—Symptoms slight, but gonococci present in numbers.

January 17th.—Discharge very slight and mucous, and number of gonococci much reduced.

January 24th.—No more symptoms of any kind, no more cocci present. After repeated examinations patient dismissed. Case cured in four weeks. This case is, of course, a failure, as far as quick cure goes; but, the patient recovered at least two weeks before we would have any right to expect it under the symptomatic treatment, and had no complications that could be ascribed to severity of method.

This concludes my list of cases, and they are none of them open to the slightest criticism on the ground of not being true cases of acute gonorrhœa. It seems to me that, from a clinical standpoint, they show as a whole vastly superior results to those obtained from the symptomatic plan of treatment. Let me briefly recapitulate the results. Out of fifteen cases, not selected, but taking them all as they came under treatment, 3 cases were cured in 1 day (Cases I., XI., XIV.), 1 case was cured in 2 days (Case VI.), 3 cases were cured in 3 days (Cases II., III., and XIII.), 1 case was cured in 5 days (Case VII.), 2 cases were cured in 6 days (Cases IV. and IX.), 1 case was cured in 18 days (Case X.), 2 cases were cured in 4 weeks (Cases VIII. and XV.), 1 case was cured in 6 weeks (Case XII.), 1 case was cured in 5 months (Case V.). Ten cases out of 15, or sixty-seven per cent. were cured inside of 6 days, and of these almost fifty per cent. in 3 days; certainly a most favorable showing. The reasons why failure occurred in some of the cases are obvious, but I cannot lengthen my paper by discussing them. I am willing to let the cases go as they stand without further comment.

Conclusions.—I summarize the whole subject-matter briefly as follows: 1. A microscopical examination of the secretion should be made at once in every case of urethral difficulty that comes before us. 2. The symptomatic plan of treatment at present generally recommended requires at least six weeks before cure is established. 3. A quick curative plan of treatment has no tenable scientific grounds against it. 4. A quick curative plan of treatment is shown to be practicable clinically. 5. The *rationale* of this plan shows it to be in harmony with the spontaneous efforts of nature to effect a cure. 6. Nitrate of silver in strong solution is the best remedy. 7. I have adduced fifteen cases, not selected, to show that in two-thirds of them a cure may be effected in from one to six days, and that not in any case did a serious complication or aggravation supervene. 8. That a quick curative treatment may be pursued in most cases that come early enough, with reasonable hope of success.

50 East Sixty-third Street.

Medical Cabinet Officers.—Our esteemed contemporary, the *British Medical Journal*, in a recent issue points out that "the new French cabinet includes two members of the medical profession, Dr. Chautemps, Minister for the Colonies, and Dr. Gadad, Minister of Agriculture. The *Journal* further states that there were "also two members of the medical profession in M. Dupuy's cabinet, namely, Drs. Lourties and Viger." In the United States we recall but a single instance of a medical man serving as a cabinet officer, that of Dr. Oliver Wolcott, of Connecticut, who was appointed Secretary of the Treasury next succeeding Alexander Hamilton, February 3, 1795, General Washington then being President. President Jefferson continued Dr. Wolcott in office, and he held it until May, 1800. It is thus seen that, unlike some of his successors, the Father of his Country had no objection to placing important public interests in the hands of a medical man, although it is only fair to mention that our Dr. Wolcott had served with great distinction in the War of the Revolution and rose to the rank of Brigadier-General. —*Journal of the American Medical Association.*

A Monument to Father Damien, the "apostle to the lepers," has been erected in Louvain, Belgium, where he was born.

Somebody Says, and has put it in print, that more physicians commit suicide than the members of any other of the learned professions.

A CONTRIBUTION TO THE STUDY OF CELLULAR THERAPY, AND THE SIGNIFICANCE AND MANAGEMENT OF FEVER IN CHILDREN.[1]

By WILLIAM JACOBSOHN, B.S., M.D.,

ATTENDING PHYSICIAN TO CHILDREN'S CLINIC, DEMILT DISPENSARY, ETC., NEW YORK.

The rapid strides that have marked the pathology of fever have brought before us various theories regarding its origin, its causes, and its significance. The limit of this paper does not permit an account of them. Professor Bouchard, of Paris, says: "The pathology of fever is concerned with what the morbid changes present are, the order in which these occur, and the relationship to one another; on the other hand, the pathogeny reveals the origin and development of fever, and the mode of action of its causes.

As one considers the pathogeny of fever of the most importance, since by its study we may understand how the first changes are brought about to produce the condition known to us as fever, I will state some of the most important factors concerning it. Again, understanding the pathogeny of fever, we can then make use of such remedies as will be rationally directed toward it.

All heat is produced by motion or activity. Be that motion in the plant or in the animal, it is that which constitutes life. The ultimate unit of life is the cell. The latter possesses sufficient individuality to have a life-history of its own. Each cell goes through the same cycle of changes as the whole organism. In health its vital powers are those of growth, nutrition, and reproduction. It accomplishes this through motion, and by the latter it evolves heat. Its movements are modified by certain conditions. Where these are normal we have a natural amount of heat production. However, under certain accidental circumstances, the cell is compelled to act more energetically, and with its increased energy there results an augmented heat production, which in the individual is manifested as fever.

In children we find cellular activity very pronounced. Not only their physical organs, but also their minds are constantly undergoing change and development. Though very active, the cells are not very stabile, and any slight impetus will affect them. As a consequence, children are very apt to get feverish and a higher degree of temperature will more readily be attained in them than in adults.

Now what prompts the cell to its extra activity? It is the principle of self-preservation against its enemies; and what are its enemies? They are the toxins, which, having gained entrance into the circulation, attack the tissues and cells, irritating them and seeking to demolish them. The cells defend themselves. If their strength is reinforced by others, which also are supplied with ammunition, *i.e.*, with a natural antitoxin, there results a struggle for existence which ends in the survival of the fittest. But this combat is not ended until there has been considerable loss, this loss being represented by that cell metabolism and degeneration which results, and which are the pathological changes. The battle has been fought and its amount of energy is represented by the heat generated, which heat is conveniently measured as so much fever. Moreover, this amount is dependent upon not only the quantity and the quality of the toxin, but also the resistance of the cell. Hence, when this resistance, which is dependent upon the stability, is less, as in children, certain toxins have a predilection for them. Consequently the toxins of infectious diseases are peculiarly liable to attack children. When the disease or fever has been absent, aborted, or modified we must attribute the change to the power of resistance in the cell. The "fit soil" of Koch is the one in which this resistance has been weakened.

[1] Read before the Society for Medical Progress of the West Side German Clinic, April 6, 1895.

As long as the activity of the cell is maintained the cell will still respond; but when it has been overstimulated, or rather extremely irritated, it no longer can react. It, as it were, is paralyzed. Exhausted, its energy is gone, its motility leaves it, and heat being less generated, we get what is called a subnormal temperature. This is illustrated in the exhaustive stages of various diseases.

Toxins which find their way into the circulation, so as to affect the cells proper, originate from the products resulting from the life and growth of micro-organisms, from the toxic matters in the air we breathe, the water we drink, and the food we eat, from the processes of fermentation that take place in the alimentary tract (these processes being due to the nutrition and life of organisms which are constantly producing toxins), from the microbes of contagions, of infections, of pyæmia, septicæmia, and the like.

We are constantly surrounded by these enemies, which seek to kill us, and when the cells become irritated by any of these toxins, or by the introduction into the circulation of organic substances, whether normal, or the result of pathological processes, we have fever. The latter has been proven by experiments with either putrid organic substances, or the various alkaloids of these, or fresh organic matter, or extracts from the muscles, spleen, kidney, etc., of healthy individuals, or certain soluble ferments of animal origin, or the products of the breaking down of corpuscles, or the products of bacterial secretion, or the body proteins of bacteria.

Having seen that fever is caused by the activity of the cells, and that the stimulation to extra action is due to their defence from substances which are threatening their stability, we conclude that fever is the result of a conservative action of nature. Consequently, to interfere, as to attempt to subdue it directly, simply for the sake of lowering the temperature, is against the laws of nature. The question, then, is, What shall we do? The answer is, remove the cause, the origin of the fever, remove those foreign substances, the toxins, if you can. Antiseptics, disinfectants, germicides have their value in very many cases. Especially in children, where gastro-intestinal troubles often give rise to increased temperature, they will find their use. But in contagious diseases these will not suffice. Something is wanted which will neutralize the poison, kill the bacillus or other microbe by its own toxin, and rid them from the system; when they disappear the cell will cease its extra activity. What is this powerful something which will do this? It is nuclein, nature's antitoxin, found in the cell, the ultimate unit of the animal organism. To it the cell owes its resisting power. Its action is as follows: If present in sufficient quantities in the cell, the latter offers enough resistance to prevent the micro-organism or its toxin from destroying it. As a consequence, the microbe, from lack of nourishment and from its own toxin, dies. The toxic products are neutralized by the nuclein; the cell now thrives without further molestation. It is the toxin that does the work of destruction; for as soon as the cell has been run down, lost its resistance and consequent immunity, *i.e.*, its sufficient amount of nuclein, it is successfully attacked, and the micro-organism devours its nutritive substance.

Let us illustrate this more fully. The bacillus diphtheriæ enters the tonsils through an abrasion, and is carried into the circulation. The healthy child has been endowed by nature with very strong vital cells, containing an abundance of nuclein. The bacillus gets its nourishment from the normal heat produced by the normal cellular activity, and is surrounded by oxygen and water. It need not attack the cell, therefore, as the food is within easy reach. But it soon secretes the products of its life, the toxins. The latter poisons attack the cells and irritate them, compelling them to protect themselves. As the toxins accumulate, in-

creased activity of the cells, viz., fever, takes place. The cells proliferate, and the circulation is increased in the parts. There is an efflux of the polynuclear white blood-corpuscles. The latter carry more nuclein to the cells, reinforcing them, and enabling all toxins to be neutralized. They also, through the power of nuclein, take hold of the micro-organisms, enveloping and imprisoning them. These micro-organisms, thus deprived of their nutrition, succumb and are carried off. The powerful phagocyte is supplied with enough nuclein to neutralize any remaining toxin. Now, if there is not a sufficient amount of nuclein in the cells and blood-corpuscles, we can see that the story will be reversed; and as the toxins will get the better of the tissues, the fever will continue, and may ultimately lead to death.

Knowing, then, that in fever we have a condition of toxæmia, we, as physicians, must assist nature to overcome this condition. In the contagious diseases, as there is the most danger to life, we should especially help by furnishing additional nuclein to the system. We can accomplish this by injecting the requisite quantity into the circulation. As it commences to act upon the system there is noticed a rise of temperature, due to the stimulation of the cellular activity. This is followed by an abrupt fall; for, as the cells are furnished with additional natural antitoxin, toxæmia is lessened. Removing the poison, it remedies the fever, and the disease is rapidly recovered from. I have used nuclein in contagious fevers. My results in diphtheria, scarlatina, and measles have been excellent. What it promises in other fevers I am not prepared to say, as these are under investigation; but nuclein has certainly a great future. My experience in the clinical study of cellular therapy has been strengthened by the additional observations on many cases in association with Dr. J. Mount Bleyer, of this city, who was the first to advocate nuclein as the defensive proteid in diphtheria. The first convincing experiments in children have been made by us. I propose shortly to report a large clinical study of fever cases in which nuclein has been used, and I must say that its clinical effect corresponds exactly to what I have above stated. So powerful is its action that I have succeeded by introducing it into the system of those exposed to contagion in warding the latter off. This, again, proves that it is *the* antitoxin, and that it is the thing which in reality produces immunity. It has also the power of aborting the disease.

Nuclein is represented chemically as $C_{29}H_{49}P_5O_{32}$. It is very rich in phosphorus, and, microscopically, presents the appearance of cell blastema, receiving carmine and cosine like all cellular substances. Its origin is in the following manner: The absorptive products of digestion are surrendered to the leucocyte; the latter from this nutritive material develops nuclein by the principle resident in the nucleus, nucleolus, etc. The products of the inorganic world are thus vitalized; the leucocyte furnishes nuclein to the various cells of the body.

The details in the administration of nuclein in fever, its doses, its indications, and its contra-indications, will be illustrated by the clinical report referred to above; the reason for such administration will then be manifest.

Before closing this paper you will permit me, gentlemen, to state that the value of the French and German antitoxin in diphtheria is due only to the nuclein which it contains, as it is made from the blood-serum which contains nuclein. Again, animal extracts all contain nuclein, and their action is one of stimulation. All these, when introduced into the circulation, produce fever, as a consequence of causing greater cellular activity. When the substance is an unattenuated toxin, pure and simple, and is introduced into the body, it also stimulates the cell; but by artificially introducing this toxin into the circulation, when toxins are already present, we must still further poison the system. The bad results which often follow the injection of the French and German antitoxin are thus explained; the good results are, fortunately, due to the presence of nuclein, though the scientists who have discovered the antitoxin have based the action on a different theory.

Vaccination does not protect because a poison has been introduced, but because something that will assist the cells to react against the disease has been introduced. Dr. Ferrán did not employ the microbe for his vaccinations; the immunity was produced by the broth into which the microbes had been introduced. Fodor showed that the blood was able to destroy bacilli. Buchner has shown that the injection of any proteid foreign to an animal organism increased the anti-biotic power of the blood. Rumpf obtained distinct therapeutic results in typhoid fever by the injection of the dead bacillus of blue pus. Klein also found many dead bacteria protection against cholera. Buchner, moreover, settled that the direct antidotal action of the antitoxin neither took place in vitreo nor in the animal organism, as has been maintained at first by Behring. The two substances, antitoxin and toxin, existed side by side, and no neutralization occurred. Antitoxin acted as a stimulus to the chemical processes of the cells, and if these cells were enfeebled in any way, their vitality lowered, the stimulation failed to rouse them, and the antitoxin was of no avail. We see, therefore, that antitoxin, like the substances Buchner, Rumpf, and Klein used, acts simply as a stimulant to increase the production of nuclein.

Just as tuberculin has failed because it contains toxins, so will the French and German antitoxin meet with unfavorable results.

That nuclein is the real therapeutic agent in diphtheria is proven by the smaller dose required, by the general condition of the patient being very much more rapidly improved, by the complications being rare, by the immediate lowering of the temperature after the initial rise, by the decrease of pulse-rate, and by the strengthening effect on mind as well as body. It acts similarly in measles and scarlatina, rapidly bringing on the rash and shortening the duration and the course of the disease.

To conclude; natural immunity is caused by enough nuclein in the body; acquired immunity is brought about by causing an increased production of nuclein, and by directly introducing nuclein into the body.

152 East Eighty-sixth Street.

DIPHTHERIA IN TENEMENTS—SEVEN YEARS' RESULTS.

By WILLIAM L. STOWELL, M.D.,

NEW YORK.

As there are almost no definite statistics of infectious diseases treated out of hospitals, I here report my diphtheria cases visited for the Demilt Dispensary.

The patients were seen at their homes (tenements) during seven years, viz., from March, 1888, to April, 1895. This is the same class that furnishes the hospital clientage, poor in physique as well as purse. The total number of patients was 16,498, of whom 177 had diphtheria. Of this number 24 died, giving a mortality of 13.55 per cent.

Lest someone might think that exudative or follicular tonsillitis passed for diphtheria I have also counted all such cases. During the same period there were 551 cases of tonsillitis exclusive of the suppurative form or quinsy. None of these died. To be sure of accuracy I counted the stubs of the death certificates. During five years the diagnosis was clinical only, but during the past two years the diagnosis has usually been confirmed by bacterial culture by the New York Health Board. These cases show diphtheria as it is and has been in unfavorable surroundings; as they occurred during a period of seven years they include several

epidemics. As the treatment varied at times the figures are not distorted by any unconscious prejudice for a particular remedy.

The results are gratifying, but the death-rate can be made to appear lower by the method of elimination adopted by advocates of a recent specific. By omitting 5 cases that died within twenty-four hours, and so were hopeless under any treatment, the mortality will read 10.73 per cent.

Treatment.—During the first three years carbolic acid with lime-water was the usual local remedy. This was used by syringe in the nose and throat of infants, but by atomizer in the older and less refractory children. During the past four years peroxide of hydrogen, diluted one-half with water, has been used exclusively. I have never used bichloride of mercury solution locally or internally that I know of. All cases had a few small doses of calomel at the beginning and tinct. ferri chlorid. subsequently. The first cases were treated with large doses of iron and chlorate of potash. Of late iron only has been given, and that in moderate doses, *e.g.*, ten drops; alcohol was not used at all. One boy was injected with Behring's antitoxin on the second day, on the third day he died.

The cases bear out the common belief that they are less fatal in private practice than in hospital. The average mortality at the Willard Parker Hospital from 1889 to 1892, inclusive, was 23.78 per cent.; for 1893 18 per cent.; for 1894, 27 per cent.

It is a curious fact that only a little more than three hundred patients were treated annually before 1893, but that year the number was 611. In 1894 703 were treated. Diphtheria has undoubtedly been very prevalent during the past year, as the death-rate from this cause was .98 per thousand living. In 1892 the diphtheria rate was .79, which was rather low. The mortality did not advance in proportion to the number of reported cases.

I conclude from these figures that antitoxin gives no better results in a long series of cases than other treatment does. Also that we must still rely upon clinical diagnosis, and only look to bacilli as to a symptom or interesting factor.

THE FIRST SYMPTOM OF PULMONARY TUBERCULOSIS, AND ITS DETECTION BY THE FEVER THERMOMETER.

By CHARLES WILSON INGRAHAM, M.D.,

BINGHAMTON, N. Y.

Not a day passes but that the fever thermometer gives additional evidence of its being one of the most accurate and scientific diagnostic instruments in both acute and chronic disease at the command of the physician and surgeon, and in the study and treatment of morbid conditions the thermometer daily strengthens the professional confidence reposed in it. Though the thermometer is but a piece of glass containing mercury, yet it diffuses information that sways the opinions of physicians in council, it indicates the best course of treatment to pursue, it decides doubtful points, and brings order and method out of confusion and uncertainty. Without departing in the least from reasonable probabilities, it is safe to say that in the practice of every physician, many lives are annually saved by what the fever thermometer has detected and brought forth for consideration. Fatal complications are averted, and unfavorable changes, particularly in the course of acute diseases, are, by its use, detected sufficiently early to allow of prompt treatment.

We cannot but wonder how our ancestors could have intelligently practised medicine and surgery without the aid of the thermometer. In the majority of doubtful cases, both as regards diagnosis and treatment, they must have been obliged to assume that they were correct, and in arriving at a convincing diagnosis they must of necessity have utilized the power of human intuition.

As a diagnostic instrument, the fever thermometer approaches more nearly the zenith of its perfection and utility in cases of suspected tuberculosis. From close observation in a large number of cases, I feel sustained in the assertion that a rise of temperature of from one-half to one degree at some period of greater or less duration every twenty-four hours, may be regarded as the first symptom of pulmonary tuberculosis. I believe that this rise of temperature, as a rule, occurs previous to every other symptom, and before the general health of the individual is influenced to a noticeable degree. Cough, with or without expectoration, night-sweats, loss of strength and weight, should be classed as secondary symptoms, as should also the appearance of positive physical signs. The only exception to this rule is when tuberculosis follows in the wake of some acute disease without intervening recovery of health. This elevation of temperature need not of necessity occur every day at the first inception of the tubercular infection, and in many cases may not occur more than two or three times a week when the disease is in an "embryonic" state, and at that stage as well as later stages the temperature will be most elevated following bodily fatigue. Excluding other morbid conditions, organic or functional, that would cause a similar elevation of temperature, we are safe to diagnose the case as one of pulmonary (or laryngeal) tuberculosis when this temperature has persisted for a period of two weeks, and is associated with loss of weight and vitality, even though there has been no accompanying cough or expectoration, and though physical examination gives negative results.

At the very beginning of tubercular involvement, with the formation of the first tubercular nodules, a condition indicated by the fever thermometer alone, is the most promising period to successfully treat the disease. At this early stage, incorrectly termed by many as pre-tubercular, the patient raises no infected sputum, which excludes the use of the microscope. At this stage the microscope may even work to the disadvantage and injury of both physician and patient, for the latter may expectorate catarrhal discharge, which even though repeatedly examined will give negative results, on the strength of which the physician assures the patient that his disease is positively non-tubercular, and thus decreases the chances of recovery. Just how long this period of "incubation" may continue without giving microscopical evidence, I do not venture to say, but it undoubtedly extends over a period of weeks and even months, varying in accordance with tissue resistance and extent or intensity of infection.

With no intention of disparaging the value of microscopical examinations as a factor in confirming the diagnosis of pulmonary tuberculosis, and with no intention of upholding clemency to physicians who neglect bacteriological researches in their relations with this disease, I do believe that the fever thermometer, in this stage of "incubation," offers us evidence not obtainable by any other known method, and as a result is more valuable than the microscope. Therefore, with a fever thermometer and a microscope in our possession, and by the intelligent use of the same, we are in a position to render tubercular subjects a most accurate and scientific diagnosis, a diagnosis unequalled in certainty, if, indeed, paralleled.

An individual who, from his depraved or impaired vitality, suspects that a tubercular process is developing in his lungs, submits his case to a physician for a confirmation or dispersion of his fears. The physician, after a careful and thorough examination—physical, symptomatic, and microscopical—finds nothing that gives proof that tuberculosis is developing. Nevertheless, the physician is not justified, before the laws of humanity and his duty to his patient, in deciding posi-

tively that the disease is non-tubercular until he has before him a complete record of the patient's temperature showing no recurring daily elevation for a period of two weeks. The patient should be instructed in the use of the fever thermometer, and should be given a blank chart with marked hours for taking the temperature, preferably at 9 and 11 A.M., and 2, 4, 6, and 8 P.M. An elevation of one-half degree occurring daily at some time during the afternoon or evening (even though it remains elevated for only a short time) for a period of two weeks, should cause a strong suspicion of tuberculosis, even though it is the only indication, and if associated with concurrent objective symptoms, even though there be no distinct physical signs, a diagnosis of incipient tuberculosis can be made with a fair degree of certainty. If the record shows a daily elevation of one degree during a similar period, a positive diagnosis of pulmonary tuberculosis (other diseases excluded) is justifiable, and will in ninety per cent. of cases be confirmed by microscopical examination at a later period. By requiring a temperature record for a period of two weeks, all liabilities of accidental elevation are eliminated, and the patient should be instructed not to carry his exercise or occupation to the extent of physical fatigue during the "temperature test."

The value of the "temperature test" is well illustrated in the following case: A lady recently came to my office and requested an examination of the chest. Because of a recent loss of strength, she believed that she was "going into consumption," as the disease had occurred in other members of her family. She had no cough of any consequence, and no expectoration, had lost little or nothing in weight, and the only reason that sustained her in the belief that she was developing consumption, was the loss of strength and vitality. Inwardly believing that she was not as badly off as she would have me think, I should have been prompted to assure her, without making an examination, that she had nothing to fear from that disease, had she not persistently adhered to her opinion.

I am reluctant to admit, though truth compels me to do so, that I did not make the examination with customary care, and finding a clear vesicular murmur, anteriorly and posteriorly, over the general surface of the lungs, I assured the lady that she was mistaken and that her lungs were in excellent condition. With unpardonable neglect I did not even take the temperature at the time of the examination. (This was before I had established my rules for the "temperature test," and before I realized its full value and importance.)

A short time later the lady returned and politely asked if it was not possible that I had overlooked some points of her case, saying that she was not as well as the week previous, and requested another examination, as she was not satisfied with my decision. Remembering my oversight of the previous examination, I took the temperature the first thing, and my surprise can be imagined when I found it to be 101.5° F. I then proceeded to give the chest a minute examination, and finally at the apex of the left lung I found a circumscribed area of consolidation, so small as to scarcely extend down to the clavicle. A short time later I was able to obtain a sufficient amount of sputum for microscopical examination, the result of which demonstrated tubercle bacilli in abundance.

It is scarcely necessary to say, that after the above experience no circumstances are too trivial to prevent my taking the temperature in every case that comes under my observation. There are, however, many unfortunate cases where the physician is not at fault. These occur in persons who are ignorant of the dangers that threaten them, or fearing the result, are afraid to have an examination made, and therefore do not bring their case to the notice of their physician until the symptoms are so far advanced that the laity have made the diagnosis.

If, after a perusal of this article, its readers will in their practice attach more importance to the initial symptoms of pulmonary tuberculosis above detailed, the object of the author is accomplished. If there is any doubt whatever about the case, give the patient the benefit of it. The physician's duty to his patient is unfulfilled, and the trust and confidence that the individual reposes in his medical adviser is painfully betrayed if the latter does not dissect and investigate beyond doubt every indication that could possibly lead to a tubercular condition.

HYPNOTISM.

By CHARLES PRENTICE, M.D.,

CHICAGO, ILL.

I DO not propose to enter any denial as to the remarkable phenomena that are exhibited in various hypnotized subjects. These are established and undeniable facts. The entire investigation of the subject of hypnotism has been confined to a study of its effects on the hypnotic subject. Prevailing through all of this has been the general superstitious idea that some mysterious force passed from the operator to the person operated upon, or from the stronger to the weaker mind, while there has been little or no effort in the direction of determining what the actual physical causes were that brought about these results. The easiest subject for hypnotism is the neurasthenic, whose general supply of vital force for various functions is very limited. Like a dynamo, the nerve-centres are capable of generating a given amount of vital force. In persons suffering from nervous debility their resources of nerve-force are restricted, and there is not sufficient to carry on with vigor the various functions throughout the animal economy. We must remember that thought or ideation, of whatever nature it may be, is a process that requires nerve-impulse for its performance, also that a pain consists of an abnormal nerve-impulse.

Suggestion that gives rise to the so-called hypnotic, psychologic or mesmeric condition may act through the medium of anyone or a combination of any of the five senses. If a person in possession of a valuable treasure was to enter an isolated house at night which he had every reason to believe was unoccupied by any other person, and while slowly feeling his way in the dark, from room to room, a hand was to be suddenly placed on his shoulder, a radical change would at once take place in his nerve-centres, varying in different individuals according to their conditions and surroundings.

If a person who was familiar with the taste of various poisons was to enter a dimly lighted apothecary shop and carelessly swallow a dose of something supposed to be a sweet cough-mixture, and the dose suddenly proved to be intensely bitter, he might at the time think he had taken a dose of strychnine and a change in the action of the nerve-centres would take place commensurate with the condition of the person and his surroundings. I have known such an accident to produce complete prostration, but when it was learned that the bitter dose was quinine, the recovery was rapid.

The smell of smoke in a high building difficult of egress might suggest the idea of a horrible death by fire, and varying conditions would result in the nervous system of the person so frightened.

Through the medium of the sense of hearing very potent changes in the nervous system are brought about. One Sabbath morning, many years ago, I was sitting on a veranda of a hotel in the South, when suddenly I heard a most terrific and unnatural sound, the building trembled violently, the air seemed dense and oppressive. For the moment I was helpless, I could

not think, I could not move; the horrible, weird strangeness of the sound had suspended my functions of volition and reason. The time was but a moment, but it seemed many to me; then, falling by me to the ground below, was the mutilated form of a man. This recalled me somewhat to my senses. There has been an explosion.

Remarkable changes are aroused in the nerve-centres through the medium of vision; intense feelings of pleasure, pain, or fear are induced by suggestion through this medium. The lover of nature is hypnotized through this medium as he looks upon some strangely grand or beautiful scene; suggestion from the inanimate surroundings has influenced the action of his nerve-centres.

Complete prostration, and often unconsciousness, are induced by something that is seen. The changes that are wrought in the nervous system by the strange and fantastic passes or movements that are made by the so-called mesmerist, hypnotist, or psychologist are no more due to a force or entity that passes from the operator to the subject, or from the stronger to the weaker mind, than that the similar mental conditions mentioned above are due to the transferrence of a like or similar entity or force. Inasmuch as a similar influence is brought out by inanimate surroundings, it demonstrates that there need be no transmission of a force to produce the hypnotic state. The influence, and resulting interesting and amusing phenomena that are induced by suggestion are commensurate with the condition of the nervous system of the subject.

After the suggestion all the changes or phenomena that take place in the subject are due to the action of forces in the nerve-centres of the subject. A belief that there is some mysterious force sent out by the operator or the stronger mind is a very foolish and dangerous one, for persons so believing are made easy subjects, and victims of persons of evil design.

When the imagination is sufficiently excited by suggestion there is so excessive a call upon the nerve-centres for vital force to sustain the exalted ideation that all other functions for the time being are robbed of the limited vital impulse that they were previously supplied with. The nerve-impulses that gave rise to the functions of feeling, motion, and reason are perverted, and where pain existed the abnormal impulse that gave rise to the feeling of pain has been turned aside and utilized in the strong imagination that has been awakened. The subject is utilizing all its feeble vital forces to maintain an excited mental condition that has been aroused by suggestion, which may be by the word of mouth, motion, general surroundings, or exciting events. Where pain is relieved by hypnotism it is because the impulse that gave rise to it has been perverted into this new channel. Where the function of feeling is suspended, it is because the vital forces have been so drawn upon that there is not sufficient left to give rise to the function of feeling. Where the reasoning faculties are so perverted that one can be made to believe, and apparently see, things as they are not, it is because the excitation has so utilized the vital forces that there is not sufficient left to assert reason, and whatever is suggested is accepted as truth. Hypnotism or suggestion is the diversion into other channels of those nerve-impulses that give rise to feeling, motion, or reason; they are turned aside from the performance of normal functions to execute another kind of work.

It is on this principle that a mustard-plaster or counter-irritant acts; it turns aside the nerve-impulses that give rise to pain, and utilizes them in the secondary or induced irritation.

"Some ideas are suggested to the mind by all the ways of sensation and reflection" (Locke).

"Suggest: To introduce indirectly to the thoughts; to cause to be thought of, usually by the agency of other objects" (Webster).

When a person steps upon a tack it suggests thoughts, and sometimes words, that are very emphatic; the savory smell of a broiling mutton-chop will often suggest hunger; the whistle of a locomotive suggests that more haste will have to be made or the train missed; whenever I hear a certain piece of music it suggests to me the lovely Jepsom Gardens and the Holly Walk at Leaming, on the River Leam, for it was there that I first heard this music; the taste of some delicious viand often suggests some other time and scene where this flavor awakened a more than ordinary appreciation; seeing another put on his gloves and hat might suggest to a man that it was time to go home. Suggestion, in its fullest sense, is susceptible of a very broad definition.

The word hypnotism, of Greek derivation, meaning sleep, is at present used in almost as broad a sense as the word suggestion, as many of the mental states that result from suggestion are denominated hypnotic. The average mind is quite as open to suggestion in the present day as it has been in all ages past. It is not capable of reasoning for itself. It generally follows out certain lines of action because they are conventional or have been suggested by others. A collegiate training is valuable to those minds capable of receiving it, for it imbues them with formulated methods of analysis and action, which methods are the results of reasoning minds that have thought for the benefit of others. What is called original thought comes to but few. "The power of stepping out of the beaten track of thought, of bursting, by a happy inspiration, through the bonds of habit and originating a new line of reflection, is most rare, and should be welcomed in spite of its sometimes becoming extravagant."

At present the people in several sections of our great republic are running wild over the question of hypnotism. Many of these unthinking minds have been led to believe that whenever a buffoon raises his hands and makes certain meaningless motions that they are bound to become helpless and follow whatever suggestions are made. Excessive fear and awe are the results of this belief, and an exalted excitation of the nerve-centres results which may actually produce what is called the hypnotic state, but where this belief does not exist, and where there is an unbelief as to this mysterious force, however weak the subject may be, these methods fail to hypnotize.

I remember a mesmerist who, several years ago, was lecturing in a small town in Ohio. He had succeeded in exciting quite a large number of the community. The audience of his nightly lectures grew until the opera-house would barely hold them. He was very much reassured by his success and invited the opinion of any member of his audience. A professional gentleman walked to the rostrum, and set forth, in a very clear and concise manner, opinions similar to those in this article. From that time his so-called hypnotic power ceased, and of the ten objects on the stage who had been obeying his suggestions, there were but two who continued to do so. These were strangers to the community, and I afterward learned from one of them that they were both under his pay at a salary of $15 per week. It is not necessary for a hypnotist to resort to this trickery, for if a firm belief in the mysterious force exists in persons of weak nervous system, they can undoubtedly be hypnotized. It is now high time for thinking professional men to come to the assistance of the unthinking masses and teach them that it is as unnecessary to yield up reason and thought to the gyration of the hypnotist's arms, as it is to the whirling of a merry-go-round.

But recently one of our courts has acquitted a murderer on the grounds that he was hypnotized. Other murderers are already taking advantage of the precedent and endeavoring to escape the penalty of their heinous crimes by assuming that they were hypnotized. In all ages of history crime has been committed.
